Abstract

This paper develops a quantitative model of bank failures to study how funding maturity and debt dilution shape balance-sheet dynamics and the timing of default. Empirically, banks approaching failure increase leverage, rely more heavily on time deposits, and experience compressing net interest margins and rising credit losses. Motivated by these patterns, the model features heterogeneous banks that choose between short- and long-maturity liabilities under limited commitment and capital regulation. Time deposits reduce rollover risk and smooth liquidity needs, but because equity can be rebuilt only through retained earnings, long-maturity funding creates incentives to dilute outstanding creditors through additional issuance. This debt-dilution channel amplifies fragility as fundamentals deteriorate, generating endogenous default and reproducing key pre-failure dynamics observed in the data. Overall, the results highlight liability-side incentives as a central driver of bank fragility.

*I am grateful to Yan Bai for her guidance and support. This project benefited from numerous conversations with George Alessandria and Matias Moretti.

1. Introduction

Banks do not fail overnight. Years before default, they exhibit a clear pattern: leverage gradually rises, net interest margins compress, and the share of time deposits steadily increases. These dynamics indicate that the liability side of the balance sheet plays an active role in shaping a bank's deterioration, rather than merely reflecting underlying distress. This paper develops a model that explains these pre-failure dynamics and quantifies the mechanisms that move banks from stability toward default.

The central premise is that banks' funding structures can be stabilizing in some environments and destabilizing in others. Short-term deposits provide flexibility but require frequent rollover, while long-term deposits—such as time deposits—offer more stable funding at the cost of future repayment obligations. In normal conditions, time deposits help smooth cash-flow and mitigate rollover risk. When profitability deteriorates and credit losses rise, however, the same long-term debt tightens balance-sheet constraints and incentivizes over-leverage, accelerating the transition toward default. Understanding this dual role of funding instruments is essential for explaining why bank distress emerges gradually and culminates in failure.

To formalize this mechanism, I develop a dynamic model in which heterogeneous banks choose between deposits and time deposits while facing liquidity shocks, capital requirements, and limited commitment. Time deposits reduce rollover risk but increase future interest expenses and repayment obligations. Default arises endogenously as declining profitability and rising credit losses erode equity, generating a stationary distribution of banks across solvency states. The model reproduces key pre-failure dynamics documented in empirical event studies of failed institutions: rising leverage, increased reliance on time deposits, compressing net interest margins, and escalating charge-offs.

A key contribution of the paper is to quantify the forces that gradually push banks toward default. Because banks in the model can raise equity only through retained earnings, their funding structure plays a central role in shaping incentives. Long-term debt not only mitigates rollover risk but also creates incentives to redistribute value from existing debt holders to equity holders through debt dilution. By issuing additional debt, banks reduce the value of outstanding long-term liabilities, effectively relaxing short-run balance-sheet constraints

while increasing future repayment obligations. This debt-dilution mechanism rationalizes the rise in leverage observed both in the model and in the data.

The quantitative role of time deposits is assessed through a sequence of counterfactual economies. In a first experiment, I remove the option to issue time deposits, forcing banks to rely exclusively on short-term funding. In this environment, banks face higher rollover risk and operate with lower leverage, but at the cost of increased vulnerability to cash-flow shocks. In a second counterfactual, I impose tighter capital requirements, which mechanically limit leverage but leave banks' incentives to dilute long-term creditors largely unchanged. Finally, I consider an economy in which banks must pay a dilution premium when issuing new time deposits, internalizing the effect of new issuance on the value of outstanding long-term liabilities. This covenant preserves the cash-flow benefits of long-term funding while eliminating dilution incentives, substantially reducing leverage cycles prior to default without affecting aggregate lending.

These results clarify why time deposits become increasingly important as banks approach distress. Early in the cycle, they allow banks to avoid forced deleveraging by smoothing cash-flow needs and reducing rollover risk. As fundamentals deteriorate and repayment obligations accumulate, however, balance-sheet flexibility declines and banks lose the capacity to absorb additional shocks. The same funding structure that initially stabilized the balance sheet begins to amplify distress, generating a gradual but accelerating path toward default—one that does not arise in models with exogenous failure or without funding frictions.

Overall, the results imply that bank deterioration is partly driven by liability-side amplification: time deposits reduce rollover risk early on but, when equity can be replenished only gradually, induce dilution incentives that make distress snowball. This state-contingent reversal yields a gradual but accelerating path toward default that is missed by frameworks with exogenous failure or frictionless funding. Policy-wise, the analysis suggests distinguishing between quantity-based constraints (Basel III capital requirements and liquidity standards such as the Liquidity Coverage Ratio) and incentive-targeting approaches that internalize dilution; the latter can complement the former by limiting pre-failure leverage cycles while preserving funding stability.

Related Literature

This paper studies how banks' liability composition evolves prior to failure and how funding maturity can endogenously amplify distress when equity issuance is slow. It contributes to empirical work on pre-failure balance-sheet dynamics, theories of runnable bank liabilities and market discipline, dynamic models of maturity choice and dilution, and quantitative analyses of bank regulation.

Empirical evidence on bank failure dynamics and funding composition. A growing empirical literature documents that failing banks exhibit systematic deterioration in fundamentals and shift toward more expensive and vulnerable funding structures before exit (Correia et al., 2023; Chen et al., 2024). My contribution is to provide a mechanism that rationalizes the joint evolution of leverage, funding composition, and profitability in the years preceding default, and to show how banks' endogenous funding choices—rather than depositor behavior alone—shape the timing of failure.

Runnable liabilities, depositor discipline, and fragility. Classic theories emphasize that demandable bank liabilities provide liquidity but can generate fragility through self-fulfilling withdrawals, while related views stress that demandable debt can discipline intermediaries by giving claimholders a liquidation threat (Diamond and Dybvig, 1983; Calomiris and Kahn, 1991; Altermatt et al., 2024). This paper complements those approaches by focusing on a liability-side channel that operates even absent runs as the dominant driver: when equity can be rebuilt only through retained earnings, the maturity structure of deposits affects banks' incentives and amplifies balance-sheet deterioration as fundamentals worsen.

Debt maturity choice and dilution incentives. A large literature studies how borrowers choose debt maturity to trade off rollover risk against ex post incentive distortions, including debt overhang and dilution (Diamond, 1991; Myers, 1977; Diamond and He, 2014; Jungherr and Schott, 2021). Recent work also emphasizes that dilution forces can arise directly in banks' deposit funding choices in dynamic environments (Jermann and Xiang, 2023). My framework builds on these insights in a banking setting with capital requirements and endogenous default: time deposits can hedge rollover risk early in the cycle, but the same long-maturity funding tightens future obligations and creates dilution incentives that

raise leverage and accelerate the approach to default as profitability deteriorates.

Bank regulation and financial stability. This paper also connects to the quantitative literature on bank regulation and systemic stability (Corbae and D'Erasmo, 2021; Begenau and Landvoigt, 2022; Lee et al., 2024). On the policy side, it relates to the Basel III framework and its liquidity standards—the Liquidity Coverage Ratio and the Net Stable Funding Ratio—which are designed to promote short-horizon liquidity resilience and stable funding profiles. The analysis highlights a distinction between quantity-based constraints such as capital and liquidity ratios and incentive-targeting policies that internalize dilution incentives, clarifying how regulation shapes not only the incidence of failure but also the path of deterioration leading up to it.

The remainder of the paper is organized as follows. Section 2 presents the empirical motivation behind the model. Section 3 presents the model environment and characterizes banks' funding and default decisions. Section 4 presents the main quantitative results and counterfactual experiments, including the role of time deposits, capital requirements, and dilution premia. Section 5 concludes.

2. Empirical Analysis

This section provides empirical evidence on the patterns of bank behavior and performance that motivate the model developed in Section 3. I begin by describing the construction of the dataset and the sources used to measure bank-level characteristics and failures. I then document how banks' funding structures and balance sheet fundamentals evolve in the years leading up to failure, using an event-study approach that compares failing and surviving institutions. The analysis highlights two key dimensions that guide the modeling framework: the shift in funding composition toward time deposits and the joint deterioration in profitability, leverage, and credit quality preceding failure.

Data Description

I use U.S. bank-level data from the quarterly *Call Reports* filed by all insured commercial banks, and I standardize several bank-specific ratios according to the definitions provided by

the Uniform Bank Performance Report (UBPR).[1] The use of the UBPR ensures consistency across banks and over time. The sample covers quarterly observations from March 2001 through March 2025.

I complement the Call Report data with the FDIC's *List of Failed Banks*, which documents all failures of FDIC-insured institutions over the same period. A bank failure is defined as either the closure of a bank by regulators or an instance of open bank assistance. Throughout my sample period, I observe 500 bank failures as reported by the FDIC.[2]

Fundamentals Around Bank Failures

In this section, I replicate the empirical analysis of Correia et al. (2023) to document how banks' fundamentals evolve in the periods leading up to failure, relative to banks that remain solvent. This exercise serves two purposes. First, it provides a benchmark for understanding the patterns of balance sheet deterioration that typically precede bank failures in the United States. Second, it allows me to assess how the behavior of key variables—such as capital ratios, loan growth, and funding composition—relates to the heterogeneity in banks' funding emphasized in my analysis.

To study the dynamics of funding, losses, and insolvency risk in the years preceding failure, I estimate variants of the following specification:

$$y_{j,t} = \alpha_j + \alpha_t + \sum_{k=-40}^{0} \mathbb{I}_{k=t}\, \beta_k + \varepsilon_{j,t}, \tag{1}$$

where $y_{j,t}$ denotes a bank-level outcome, k measures the number of quarters to failure, and α_j and α_t are bank and time fixed effects, respectively. The benchmark period is set to $k = -40$, corresponding to ten years before failure, so all coefficients are measured relative to that date. The sequence of coefficients $\{\beta_k\}$ captures the average deviation of failing banks from solvent ones over time, holding constant bank-specific heterogeneity and aggregate shocks.

Funding. Figure 1 plots the evolution of banks' funding composition in the ten years preceding failure. The figure displays the estimated event-study coefficients for time deposits

[1] For more details on the FFIEC's UBPR and the construction of these variables, see `https://cdr.ffiec.gov/public/DownloadUBPRUserGuide.aspx`.

[2] For more detailed information checking my Appendix section

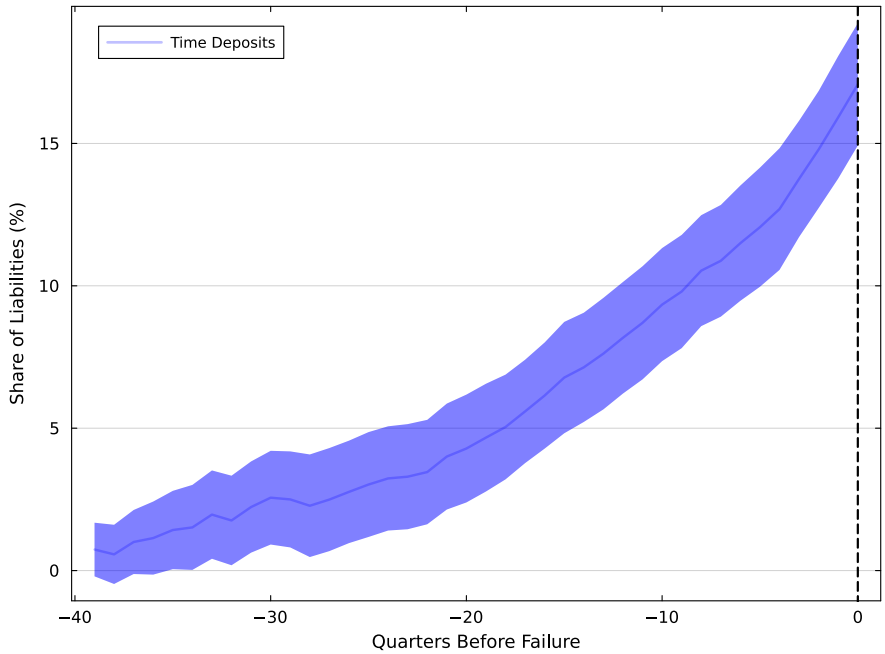

Figure 1: Time deposits (% of total liabilities) before bank failure

relative to solvent banks, controlling for bank and time fixed effects. A clear pattern emerges: as banks approach failure, the share of time deposits rises sharply, indicating a shift toward illiquid and higher-yield liabilities. These patterns show that as financial distress intensifies, banks substitute away from demand deposits toward costlier and less liquid sources.

Leverage. Figure 2 documents the evolution of banks' leverage in the ten years preceding failure. The figure reports event-study coefficients for the ratio of total liabilities to assets.

A clear pattern emerges: as banks approach failure, leverage rises steadily and accelerates in the final years before default. This increase coincides with an expansion of time-deposit funding, which accounts for the bulk of the leverage buildup.

These dynamics imply that distressed banks raise leverage by shifting their liability structure toward longer-maturity deposits. By offering higher yields to retail depositors, banks are able to expand balance sheets even as default risk increases, locking in funding while accumulating future repayment obligations. The resulting rise in leverage is gradual but systematic, consistent with a deterioration process driven by liability-side amplification rather than sudden funding runs.

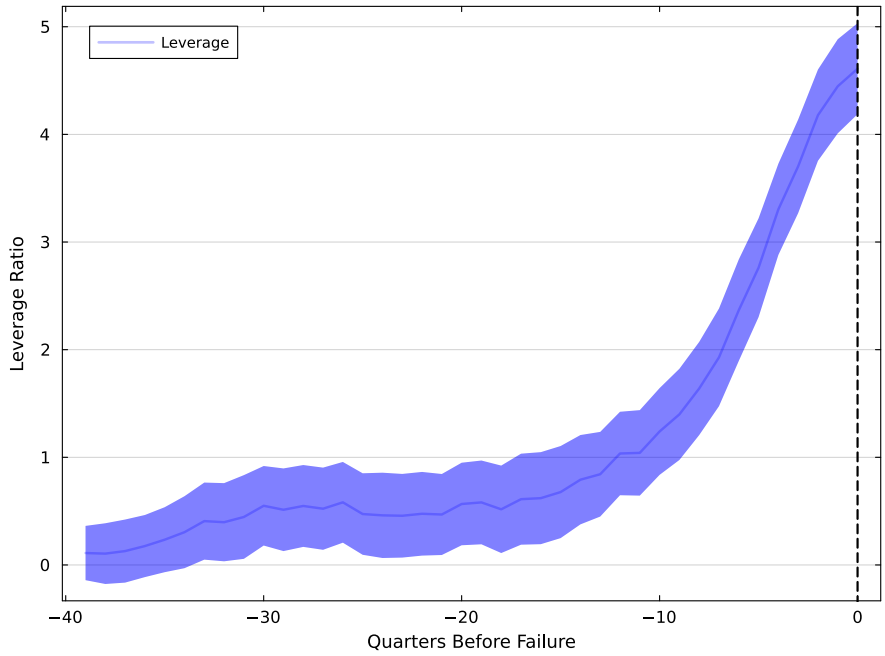

Figure 2: Liabilities (% assets) before bank failure

Net Interest Margin. Figure 3 plots the evolution of banks' net interest margins in the ten years preceding failure. The figure reports event-study coefficients for net interest income relative to interest-earning assets.

Two distinct phases emerge. First, despite a sustained increase in leverage documented in Figure 2, net interest margins remain stable and statistically indistinguishable from those of solvent banks for most of the pre-failure period. Second, approximately ten quarters before failure, net interest margins begin to decline sharply and turn negative, with losses deepening as default approaches.

This sequencing indicates that rising leverage precedes the collapse in profitability. As banks expand liabilities using longer-maturity funding, funding costs gradually increases while interest income also adjusts. Only once leverage reaches sufficiently high levels do higher interest expenses dominate, causing net interest margins to compress and eventually become negative.

These results highlight a gradual deterioration process in which balance-sheet expansion occurs well before profitability collapses. The delayed but sharp decline in net interest

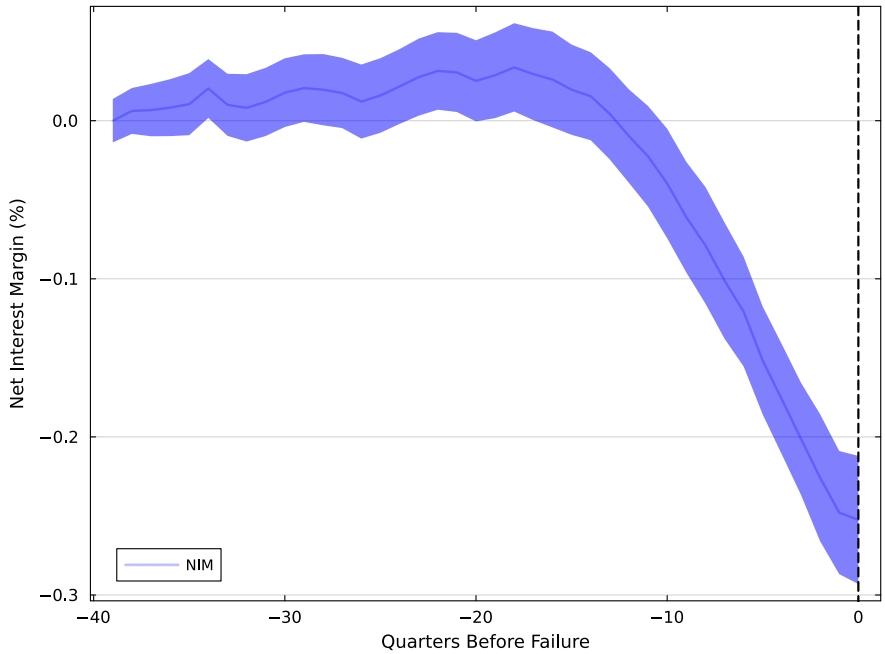

Figure 3: Net Interest Margin before bank failure

margins is consistent with a liability-side amplification mechanism rather than an abrupt shock to earnings.

Losses. Figure 4 plots the dynamics of realized loan losses in the ten years preceding failure. The figure reports event-study coefficients for net charge-offs estimated relative to solvent banks, after controlling for bank and time fixed effects.

The patterns reveal a clear sequencing in the deterioration process. Net charge-offs begin to rise approximately fifteen quarters before failure and continue to accelerate thereafter, indicating a gradual deterioration in asset quality that precedes the collapse in profitability. Consistent with this pattern, net income declines persistently and turns negative several quarters before failure, as documented above.

Together, these dynamics document a prolonged weakening of asset quality and earnings leading up to bank failure. The early increase in loan losses—followed by rising leverage and a delayed collapse in profitability—is consistent with a gradual deterioration process rather than an abrupt shock.

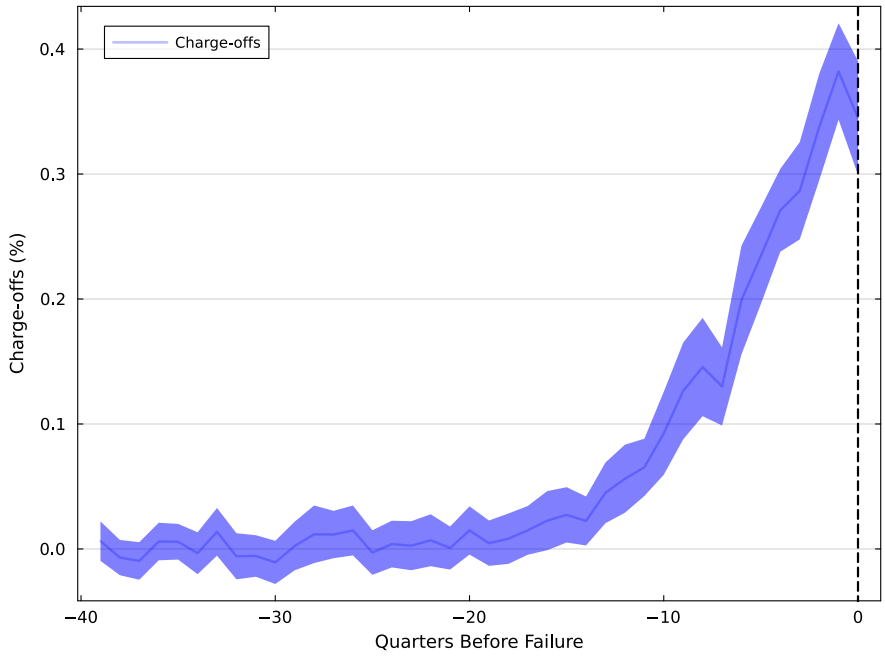

Figure 4: Loan losses (% of loans) before bank failure

These findings motivate a framework in which banks' solvency deteriorates endogenously through the interaction of credit losses, funding choices, and profitability. The early rise in loan losses, followed by a sustained increase in leverage and a delayed collapse in net interest margins and net income, indicates that bank failure is preceded by a prolonged period of balance-sheet adjustment rather than an abrupt shock.

In particular, the evidence suggests that losses weaken net worth well before failure, while banks respond by expanding leverage and altering the composition of their liabilities. As funding shifts toward longer-maturity and more expensive instruments, funding costs accumulate gradually. Only later do these higher costs dominate interest income, leading to sharply negative net interest margins and accelerating net income losses. This sequencing highlights the joint role of loss realization and liability-side dynamics in shaping the path to default.

In the model that follows, I formalize these mechanisms by allowing banks' balance sheets to respond endogenously to shocks affecting loan returns and funding costs, which jointly

determine the evolution of net worth and default risk.[3]

Overall, the empirical evidence reveals two key patterns that guide the theoretical analysis. First, banks approaching failure reallocate funding toward longer-maturity and costlier liabilities. Second, solvency deteriorates gradually as early losses weaken balance sheets and rising funding costs compress profitability over time. Together, these patterns point to a tight interaction between funding structure and solvency dynamics. The next section develops a model that captures this interaction, allowing funding composition, loan performance, and default risk to co-evolve within a unified framework.

3. Model

This section develops a model of financial intermediation to study how banks' financial frictions interact with their endogenous default decisions. The framework features entrepreneurs seeking external financing for risky projects, competitive households allocating savings across assets, and banks that intermediate funds between the two sectors. The interplay between imperfect competition, regulatory constraints, and wholesale funding frictions generates the dynamics observed in the periods preceding bank failure.

Entrepreneurs face a static discrete choice problem when deciding whether to finance a risky project through bank borrowing. Households are competitive and can save either in deposits or in long-term bank liabilities. Banks act as intermediaries by accepting funds from households and extending loans to entrepreneurs. The economy produces a single final good, and all variables are expressed in units of consumption of this good.

Banks face several frictions that govern their funding life cycle. First, imperfect competition in the loan market allows banks to set lending rates to maximize profits. Second, regulatory constraints impose capital requirements that compel banks to manage their lending and funding decisions intertemporally, maintaining sufficient cash buffers against potential capital shortfalls. Third, time deposits represent a more costly funding source, reflecting both their longer maturity and greater exposure to default risk.

[3] Appendix Figure A.1 shows that the increase in time deposits—implying longer liability maturity—is not accompanied by an increase in asset maturity. In fact, asset maturity declines, indicating that banks closer to failure face lower, not higher, interest rate exposure.

Households

The economy features a representative household whose lifetime utility is given by

$$E_0\left[\sum_{t=0}^{\infty}\beta^t \log(C_t)\right].$$

where β is the discount factor and C_t is their consumption. The household owns all banks in the economy. I study the perfect foresight transition paths with respect to aggregate states, so the stochastic discount factor and the real interest rate are linked through the Euler equation for savings, $\Lambda_{t+1} = \frac{1}{R_{f,t}}$, where $R_{f,t}$ is the risk-free rate set by the monetary authority.

The household supplies labor to firms at wages W_t and rents capital via entrepreneurs. The household has a limited supply of labor $\bar{L} = 1$. It also saves by buying deposits, D, and certificates of deposits, B, from banks. They receive dividends from the banks and are taxed lump-sum. They fund new banks by transferring some equity, denoted by $\bar{n}$, so they can start their operation.

Firms

The economy is populated by a representative final-good firm that rents capital from entrepreneurs at rate $R_{K,t}$ and hires labor at wage W_t to operate a constant-returns-to-scale production technology:

$$Y_t = \bar{p}_t K_t^{\alpha} L_t^{1-\alpha}, \tag{2}$$

where $\bar{p}_t$ represents an aggregate *capital-quality shock* that affects both the productivity of capital and the expected success rate of entrepreneurial projects.

The firm's static profit-maximization problem is

$$\max_{K_t, L_t} \; \bar{p}_t K_t^{\alpha} L_t^{1-\alpha} - W_t L_t - R_{K,t} K_t. \tag{3}$$

The first-order conditions imply:

$$W_t = (1-\alpha)\bar{p}_t \left(\frac{K_t}{L_t}\right)^{\alpha}, \tag{4}$$

$$R_{K,t} = \alpha\bar{p}_t \left(\frac{L_t}{K_t}\right)^{1-\alpha}. \tag{5}$$

Assuming labor supply is normalized to $L_t = 1$, equilibrium wages and the rental rate of capital are

$$W_t = (1-\alpha)\bar{p}_t K_t^{\alpha}, \tag{6}$$

$$R_{K,t} = \alpha\bar{p}_t K_t^{\alpha-1}. \tag{7}$$

The rental rate $R_{K,t}$ determines the aggregate return to capital paid to entrepreneurs. Consistent with the entrepreneurial problem described below, the gross return on entrepreneurs' capital claims is given by:

$$R_{E,t+1} = \frac{R_{K,t+1}}{\bar{p}_t} + (1-\delta) = \alpha K_t^{\alpha-1} + (1-\delta), \tag{8}$$

where $(1-\delta)$ denotes the resale value of undepreciated capital. This formulation captures that when the quality of capital, $\bar{p}_t$, is high, the effective return received by entrepreneurs—normalized by capital quality—remains unchanged. Hence, only the firm's production technology depends on the aggregate capital-quality shock $\bar{p}_t$.

This relationship arises because entrepreneurs are subject to limited liability and may default on their obligations. As a result, the aggregate return to entrepreneurial capital is determined solely by the production technology and the effective depreciation of assets, rather than by the realized capital quality itself. The role of limited liability in implying this outcome will become clearer in the next subsection.

Entrepreneurs

The entrepreneurial sector consists of two-period entrepreneurs who finance investment through bank loans. Each entrepreneur belongs to a distinct bank pool, and there is no

interbank competition or mobility across pools. The set of entrepreneurs linked to bank j constitutes its *client pool*, capturing the bank's local market power, consistent with recent empirical evidence.

Each pool contains a unit mass of entrepreneurs indexed by $i \in [0, 1]$. Entrepreneurs are risk-neutral and maximize expected profits, which are ultimately transferred to the household sector.

In period t, each entrepreneur borrows $\bar{k}$ units of the final good from a bank to purchase risky capital claims priced at 1. Hence,

$$k_t^i = \bar{k}.$$

The capital claim yields a stochastic return per unit of loan given by:

$$R_{E,t+1} = \alpha K_t^{\alpha-1} + (1 - \delta),$$

where $\alpha K_t^{\alpha-1}$ is the aggregate rental rate of capital determined by firms—abstracting from the quality shock—and $(1 - \delta)$ represents the resale value of undepreciated capital. If the project succeeds, entrepreneurs receive this gross return; if it fails, the payoff is zero due to limited liability. Thus, the realized return on entrepreneurs' capital claims depends on the project's success state, while the expected return reflects both the production technology and the probability of repayment.

At the beginning of every period, each entrepreneur draws an idiosyncratic return x_t^i upon investment success, which is public information and expressed as a share of the borrowed amount $\bar{k}$. Banks observe x_t^i, but must charge a uniform loan rate within each pool.

Suppose entrepreneur i belongs to bank j's client pool, which faces a common project success probability $p_{t+1}^j(z_{t+1}, x_t^\star)$. The variable z_{t+1} denotes a *bank-specific state*, capturing idiosyncratic credit risk conditions or shocks to bank j's balance sheet. The function $p_{t+1}^j(z_{t+1}, x_t^\star)$ represents the probability that projects financed by bank j succeed, conditional on its state z_{t+1} and on the cutoff entrepreneur $x_t^\star$. The cutoff $x_t^\star$ reflects the risk composition of the bank's loan portfolio: when the marginal project offers higher expected returns, it also entails greater risk, thereby lowering the pool's overall success probability. Aggregating across

the continuum of banks, the economy-wide success probability is given by the mass-weighted average

$$\bar{p}_{t+1} = \int_0^1 p^j_{t+1}(z^j_{t+1}, x^{j\star}_t) d\mu^j,$$

which represents the expected share of successful projects in the aggregate banking system.

The project's gross return per unit of loan is therefore:

$$\begin{cases} R_{E,t+1} + x^i_t, & \text{with probability } p^j_{t+1}(z_{t+1}, x^\star_t), \\ 0, & \text{with probability } 1 - p^j_{t+1}(z_{t+1}, x^\star_t). \end{cases} \tag{9}$$

The gross return is $R_{E,t+1} + x^i_t$ in the successful state and 0 in failure, implying full loss of capital.[4] The success probability $p^j_{t+1}(z_{t+1}, x^\star_t)$ is i.i.d. across entrepreneurs within a pool but correlated across time through the evolution of z_{t+1}.[5] The failure rate within each pool is $1-p^j_{t+1}(z_{t+1}, x^\star_t)$, and aggregation across all banks yields the unconditional failure probability $1 - \bar{p}_{t+1}$.

Entrepreneurs cannot switch across banks. Given the loan rate $R^j_{\ell,t}$, each entrepreneur decides whether to borrow and invest. They must repay $R^j_{\ell,t}$ if they borrow, and due to limited liability, their payoff is bounded below by zero. Table 1 summarizes the payoff structure.

Table 1: Entrepreneur's Problem (conditional on investing)

State	Receive	Pay	Probability
Success	$R_{E,t+1} + x^i_t$	$R^j_{\ell,t}$	$p^j_{t+1}(z_{t+1}, x^\star_t)$
Failure	0	0	$1 - p^j_{t+1}(z_{t+1}, x^\star_t)$

Since $R^j_{\ell,t} > 1$, entrepreneurs cannot repay if their project fails, and the bank seizes the remaining capital claim, which has zero value.

[4]This setup maps to Coimbra and Rey (2024), where capital return equals $R_{K,t} + (1 - \delta)$. I interpret $\bar{p}_t$ as an aggregate capital-quality shock, with an increased credit risk component as Corbae and D'Erasmo (2021).

[5]This structure parallels Vasicek (2002), often used in regulatory credit-risk modeling.

The expected payoff of entrepreneur i conditional on borrowing at rate $R^j_{\ell,t}$ is

$$\pi_t(R^j_{\ell,t}) = E_t\big[p^j_{t+1}(z_{t+1}, x^\star_t)\big(R_{E,t+1} - R^j_{\ell,t} + x^i_t\big)\bar{k}\big].$$

If entrepreneurs do not invest, they forgo x^i_t. Hence, their decision rule is

$$U^e = \max_{h\in\{0,1\}} h\,\pi_t(R^j_{\ell,t}),$$

where h is the binary investment choice. An entrepreneur invests if and only if

$$R_{E,t+1} + x^i_t \geq R^j_{\ell,t}, \tag{10}$$

i.e., when the expected project return exceeds the loan rate.

Loan Demand. With no interbank competition or mobility, each bank j faces a unique loan demand function. From the investment rule in Equation 10 and the distribution of x^i_t, loan demand per unit of capital is

$$\ell^d(R^j_{\ell,t}, R_{E,t+1}) = \Pr\big(x^i_t \geq R^j_{\ell,t} - R_{E,t+1}\big)\bar{k}. \tag{11}$$

The marginal entrepreneur is defined by the indifference condition $x^\star_t = R^j_{\ell,t} - R_{E,t+1}$. Since x^i_t follows a known distribution, the loan demand corresponds to the complementary cumulative distribution function of x^i_t evaluated at $x^\star_t$. Thus, loan demand increases with $R_{E,t+1}$ and decreases with $R^j_{\ell,t}$: higher project returns or lower lending rates raise the share of entrepreneurs willing to invest.

Banks

There is a continuum of banks of measure one, indexed by $j \in [0,1]$, all owned by the representative household. Each bank is operated by a manager who makes decisions regarding entry, default, lending, and funding. The manager seeks to maximize the expected discounted stream of dividend payments, div_t, according to the objective function:

$$E_0\left[\sum_{t=0}^{\infty} \sigma^t \Lambda_t, div_t\right],$$

where Λ_t denotes the household's stochastic discount factor and $\sigma \in (0, 1]$ captures the manager's degree of myopia. When $\sigma < 1$, managerial myopia introduces a potential agency friction between the bank manager and the household, as in Corbae and D'Erasmo (2021). To ensure a well-defined cross-sectional distribution of banks, I impose the condition $\sigma \Lambda_{t+1} R_{f,t} < 1$, which is standard in incomplete market environments. Here, $R_{f,t}$ denotes the risk-free rate.

Assets. To model bank solvency risk, I begin by characterizing the composition of bank assets. Each bank invests in loans that yield an agreed-upon gross interest rate $R^j_{\ell,t}$. Let ℓ^j_{t-1} denote the stock of loans extended by bank j in period $t-1$ at rate $R^j_{\ell,t-1}$. The value of bank j's assets at time t is given by:

$$a^j_t = p(z^j_t, R^j_{\ell,t-1} - R_{E,t+1}) R^j_{\ell,t-1} \ell^j_{t-1}, \tag{12}$$

where $p(\cdot)$ is the fraction of performing loans that are repaid. Defaulted loans are realized as losses on the bank's balance sheet, and $1 - p(\cdot)$ represents the share of charge-offs. I assume that z^j_t follows a persistent AR(1) process, capturing cyclical variation in credit risk across banks.

Resources. Bankers use their cash-on-hand (n), deposits (d), and time deposits (b) to finance new loans $\ell(R^j_{\ell,t}, R_{E,t+1})$ at the interest rate $R^j_{\ell,t}$.

Time deposits are long-term instruments that do not fully mature within a single period. A fraction λ of their principal is repaid each period, while the remaining share $1 - \lambda$ remains outstanding. Debt holders receive a coupon payment c on the outstanding amount. Deposits, in contrast, are short-term contracts that fully mature each period.

Given their balance sheet positions, a bank's cash-on-hand evolves according to

$$n^j_t = a^j_t - \omega^j_t(\ell^j_t + \phi) - d^j_t - (\lambda + c) b^j_t. \tag{13}$$

Here, a^j_t denotes the value of bank j's assets; ω^j_t is an idiosyncratic shock affecting cash flows, scaled by the amount of loans and a constant ϕ; d^j_t represents deposit payments inherited from the previous period; and $(\lambda + c) b^j_t$ corresponds to repayments on maturing time deposits and coupon payments.

The idiosyncratic shock ω^j_t introduces cross-sectional heterogeneity across banks, following

Ottonello and Winberry (2020). This shock also helps match the empirical distribution of default rates observed in the data. I assume that ω_t^j is independently and identically distributed across banks and time, according to

$$\omega_t^j \sim \mathcal{N}(0, \eta_\omega^2).$$

Intuitively, ω_t^j captures fluctuations in cash flows that generate liquidity needs at the bank level.

Equity. At the beginning of each period, the bank's book equity is defined as the value of its cash-on-hand net of the outstanding amount of long-term debt, discounted at its present value:

$$e_t^j = n_t^j - q_{b,t}^{rf}(1-\lambda)b_t^j, \tag{14}$$

where $q_{b,t}^{rf}$ denotes the risk-free price of long-term liabilities.

This specification implies that when equity is evaluated at fair value, the bank's liabilities are also marked to fair value rather than to market value. This assumption is consistent with the regulatory treatment of Tier 1 capital, under which banks may include unrealized gains from changes in the fair value of their liabilities, excluding those arising from their own credit risk. Consequently, discrepancies can emerge between the fair value and the market value of equity.

Resource Constraint. Banks use their cash-on-hand and liability issuance to finance new lending, giving rise to the following per-period resource constraint:

$$div_t^j + \ell^d(R_{\ell,t}^j, R_{E,t+1}) = n_t^j + q_{d,t}d_{t+1}^j + q_{b,t}\big(b_{t+1}^j - (1-\lambda)b_t^j\big) - \psi - Z(d_{t+1}^j, b_{t+1}^j, b_t^j). \tag{15}$$

Equation (15) describes the bank's flow-of-funds constraint. On the left-hand side, dividends div_t^j and new lending $\ell^d(R_{\ell,t}^j, R_{E,t+1})$ represent the uses of funds. The loan demand function $\ell^d(\cdot)$ is derived from the entrepreneurs' problem and links the bank-specific lending rate $R_{\ell,t}^j$ to the expected return on entrepreneurial projects $R_{E,t+1}$ (see Equation 11).

On the right-hand side, n_t^j denotes the bank's net worth entering the period. The terms $q_{d,t}d_{t+1}^j$ and $q_{b,t}\big(b_{t+1}^j - (1-\lambda)b_t^j\big)$ capture the funds raised through deposits and time deposits,

respectively. The expression $b^j_{t+1} - (1-\lambda)b^j_t$ corresponds to the net issuance of time deposits, where λ is the maturity parameter governing the fraction of long-term liabilities that expires each period.

Banks incur operating costs associated with serving depositors, such as labor expenses. I assume that these costs are linear in deposits,

$$Z(d^j_{t+1}) = \zeta\, d^j_{t+1},$$

where $\zeta > 0$ denotes the marginal servicing cost. A similar specification is adopted in Wang et al. (2022).

In addition, I assume that banks cannot repurchase their outstanding stock of time deposits, i.e.,

$$b^j_{t+1} - (1-\lambda)b^j_t > 0.$$

Using the cash-on-hand equation 13 and fair value equity 14, we can determine next period equity by [6]

$$e^j_{t+1} = a^j_{t+1} - d^j_{t+1} - (\lambda + c + (1-\lambda)q^{rf}_{b,t+1})b^j_{t+1}.$$

A key friction in the model is the assumption that banks are unable to issue equity, which necessitates that dividends must always be non-negative, expressed as:

$$div^j_t \geq 0.$$

This constraint prevents banks from raising equity to substitute deposits or long-term liabilities for funding their lending activities. Additionally, it highlights the limited liability of banks, as they have the option to default on their debt, resulting in equity holders losing their entire investment.

[6] Here I am implicitly assuming that revenue shock, for example, unrealized losses, does not interact with the requirements over capital tomorrow. This is in line with the reporting on capital tier ratio from Schedule RC-R, for which only unrealized losses on securities and debt securities are accounted.

Capital requirement. The next key ingredient in my model is regulation, captured by a capital requirement:

$$e^j_{t+1} \geq \kappa\, a^j_{t+1}. \tag{16}$$

Equation (16) requires a bank's fair-value equity at the beginning of period $t+1$ to be at least a fraction κ of its total assets. Consistent with regulatory practice under Tier 1 capital requirements, I allow banks to continue operating while violating this requirement, but such violations must come only from the liquidity needs of banks originated from the ω shock.

Due to the no-equity investment and the capital constraints, banks will need to smooth their cash-holding to avoid states with low liquidity and, thus, default.

Lastly, notice that all constraints are linear on the constant $\bar{k}$. Therefore, we can normalize all variables at the bank level by $\bar{k}$. Consequently, to solve the bank problem, we are only required to know aggregate variable $R_{E,t+1}$ in the steady state. As a simplification to speed up the computational process, I calibrate the steady $R_{E,t+1}$ to match the banks' net interest margins, while $\bar{k}$ is obtained as a residual of the entrepreneur return.

Debt Pricing

Households competitively lend resources to banks at the price schedules $q_d(z_t, R_{\ell,t}, d_{t+1}, b_{t+1})$ and $q_b(z_t, R_{\ell,t}, d_{t+1}, b_{t+1})$.

Banks cannot distinguish between the types of debt on which they default. If they default on deposits, they must also default on time deposits, and vice versa. The default decision of bank j is denoted by $h(z_t, n_t, b_t)$, where (z_t, n_t, b_t) are the bank's state variables.

A key distinction between deposits and time deposits arises from the presence of deposit insurance. Since, on average, roughly half of time deposits exceed the insurance limit, they are more exposed to default risk. To capture this feature, I assume a repayment hierarchy that guarantees the repayment of depositors before time deposit holders in the event of default.[7]

The process unfolds as follows. Whenever a bank defaults, debt holders take control of the bank's assets. Assets are liquidated with a recovery rate $\gamma \in (0, 1)$. Depositors are paid first,

[7] This assumption follows the hierarchy of claims established by the FDIC.

and any remaining funds after covering deposits are distributed to time deposit holders, who receive

$$\max\{0,\, \gamma a_t - d_t\}.$$

Banks are required to pay insurance premiums to a regulator, net of the expected recovery on assets. The insurance premium is fairly priced, taking into account the bank's lending, debt, and default decisions. Consequently, deposits are priced net of this insurance premium. After liquidation, any unrecovered portion of assets is transferred lump-sum to the household sector; thus, there is no aggregate welfare loss from default.

Since households hold these liabilities, they discount them using the stochastic discount factor Λ_t. The price of deposits, net of the insurance premium, is therefore given by:

$$\begin{aligned} q_d(z_t, R_{\ell,t}, d_{t+1}, b_{t+1}) = E_t\{\Lambda_{t+1}\,[1 - h(z_{t+1}, n_{t+1}, b_{t+1}) \\ + h(z_{t+1}, n_{t+1}, b_{t+1}) \min\{1, \gamma a_{t+1}/d_{t+1}\}]\}. \end{aligned}$$

Similarly, the price of time deposits is given by:

$$\begin{aligned} q_b(z_t, R_{\ell,t}, d_{t+1}, b_{t+1}) = E_t\{\Lambda_{t+1}[(1 - h(z_{t+1}, n_{t+1}, b_{t+1}))(\lambda + c + (1-\lambda) q_{b,t+1}) \\ + h(z_{t+1}, n_{t+1}, b_{t+1}) \min\left\{ c + \lambda + (1-\lambda) q^{rf}_{b,t}, \frac{\max\{0, \gamma a_{t+1} - d_{t+1}\}}{b_{t+1}} \right\}\Big]\Big\}, \end{aligned}$$

where $q_{b,t+1}$ denotes the price of time deposits next period.

Bankers' Recursive Problem

Since the banker's problem is identical across banks, I drop the index j. The state vector (z, n, b) summarizes the bank's relevant variables: the idiosyncratic shock to the share of performing loans z, cash-on-hand n, and outstanding time deposits b. Bankers lack commitment and may default on their debt obligations. The value of operating the bank is therefore given by:

$$V(z, n, b) = \max_{h \in \{0,1\}} (1 - h)\, V^c(z, n, b),$$

where h is the default indicator, $h(z, n, b)$ denotes the corresponding default rule, and $V^c(\cdot)$ represents the continuation value of remaining solvent. If the banker defaults, the value is zero.

The continuation value satisfies the following recursive problem:

$$
\begin{aligned}
V^c(z, n, b) = \max_{R_\ell,\, d',\, b'} & \left\{ div + E_{z'|z}[\sigma \Lambda_{t+1} V(p', n', b')] \right\} \\
\text{s.t. } & div = n - \ell^d(R_\ell, R'_E) + q_d d' + q_b(b' - (1-\lambda)b) - Z(d') \geq 0, \\
& a' = p(z', R_\ell - R'_E) R_\ell \, \ell^d(R_\ell, R'_E), \\
& e' \geq \kappa a', \\
& e' = a' - d' - (\lambda + c + (1-\lambda) q_b^{rf}) b', \\
& n' = a' - \omega'(\ell^d(R_\ell, R'_E) + \phi) - d' - (\lambda + c) b', \\
& b' - (1-\lambda) b \geq 0.
\end{aligned}
$$

The bank chooses its loan rate R_ℓ, deposit issuance d', and time deposits b' to maximize its expected discounted value, subject to the non-negativity of dividends, regulatory capital requirements, and the law of motion for assets and equity. All expectations are conditional on the current loan-performance state z.

Default Characterization

Banks face the possibility of default whenever their continuation value becomes non-positive. Because dividend payments must be non-negative, the continuation value $V^c(z, n, b)$ is positive for any feasible combination of (z, n, b) that satisfies the resource and feasibility constraints. When these constraints cannot be met—due to insufficient net worth or excessive leverage—the bank optimally defaults.

Formally, let Ω denote the set of feasible states. The *default region* is defined as:

$$\mathcal{H} = \{(z, n, b) \in \Omega : V^c(z, n, b) \leq 0\}.$$

In this region, the value of continuing operations falls below zero, and the banker chooses to

default. Default implies liquidation of the bank and a payoff of zero to the banker, reflecting limited liability.

Hence, the bank's overall value function satisfies:

$$V(z, n, b) = \max\{V^c(z, n, b),\ 0\},$$

where $V^c(z, n, b)$ denotes the value of continuing operations and the zero value represents default. The boundary between the continuation and default regions defines the *endogenous default threshold*, which determines the states under which a bank remains solvent.

Finally, default occurs only when the continuation value $V^c(z, n, b)$ is *not feasible*, i.e., when no combination of (R_ℓ, d', b') satisfies the resource and feasibility constraints while maintaining non-negative dividends. In such cases, the bank cannot continue operations, and default becomes the only admissible outcome.

The banking sector features endogenous exit through default and immediate entry of replacement banks, guaranteeing a stationary distribution of banks. A full characterization of the distributional law of motion and the stationary competitive equilibrium is provided in Appendix B.

4. Quantitative Analysis

In this section, I examine the quantitative implications of the model developed in Section 3. The goal is to assess whether the framework can replicate key features of the U.S. banking sector and generate realistic differences in banks' balance sheets and performance.

The analysis proceeds in three steps. First, I calibrate the model to match targeted moments that describe the empirical distribution of bank characteristics, such as leverage, funding composition, and profitability. Second, I assess the model's ability to reproduce untargeted life-cycle dynamics before default, comparing simulated patterns of leverage, funding, and profitability with those observed in the data. Finally, I conduct counterfactual exercises to study how funding structure and capital regulation influence banks' risk, funding choices, and stability.

Overall, these exercises show that the model captures important aspects of balance-sheet

heterogeneity and bank fragility, providing a useful framework for analyzing the interaction between funding, default risk, and regulation.

Computation

The model described in Section 3 features heterogeneity across banks and important nonlinearities. All nonlinearities arise from the bank's problem due to the endogenous default decision and the sometimes binding constraints. Due to these nonlinearities, I rely on global methods to solve the model (value function iteration).

Even after reducing the problem to a stationary equilibrium, the model features three individual state variables at the bank level: (z, n, b) and three choice variables (R_ℓ, d', b') and is therefore subject to the curse of dimensionality. [8] The algorithm for solving the model relies on graphics processing units (GPUs) to highly parallelize the solution.

Parameterization

The model calibration proceeds in two steps. First, a subset of parameters is directly obtained from the data, while the remaining parameters are estimated using the Simulated Method of Moments (SMM). As discussed later, the selected set of moments is chosen to capture the key financial frictions faced by banks. Throughout, one model period corresponds to a quarter, so all parameters and targets are expressed at a quarterly frequency.

The primary data source is the FFIEC *Call Reports*. I begin by parameterizing the stochastic process for loan losses.[9] Let $\text{nco}_{j,t}$ denote net loan charge-offs divided by total loans for bank j at time t, and define the implied loan-survival share

$$p_{j,t} \equiv 1 - \text{nco}_{j,t} \in (0, 1].$$

I estimate the following AR(1) process for $\log p_{j,t}$:

$$\log p_{j,t} = \mu_p + \rho_p \log p_{j,t-1} + u_{j,t}, \qquad u_{j,t} \sim \mathcal{N}(0, \eta_p^2).$$

[8] In the Appendix C, I cover how I compute the policies and steady-state distribution of banks.

[9] For consistency with the model, I restrict the sample to banks that realize loan losses in at least 95% of the observed quarters.

Given (μ_p, ρ_p, η_p), I discretize the latent AR(1) process using the method of Tauchen (1986) on the $\log p$ scale and map back to levels via $p = \exp(\cdot)$, truncating the support to $p \leq 1$.

To allow loan performance to depend on lending conditions, I let the effective loan-survival probability depend on the lending rate R_ℓ according to

$$p(z, R_\ell) = \min\{\exp(\log z + \rho_R(R_\ell - R_E^\star)),\ 1\},$$

where z denotes the baseline survival realization drawn from the discretized process, ρ_R governs the sensitivity of loan performance to the lending rate, and $R_E^\star$ normalizes the steady-state lending rate. ρ_R is calibrated to match the average net loan losses when a bank fails.

An essential parameter for the model is the average maturity of time deposits. Following the literature, I assume a maturity of one year, which implies $\lambda = 1/4$ in quarterly terms.

The loan demand function is parameterized by assuming that the idiosyncratic component x_t^i follows a logistic distribution, yielding

$$\ell^d(R_{\ell,t}, R_{E,t+1}) = \frac{1}{1 + \exp[\theta(R_{\ell,t} - R_{E,t+1})]}, \tag{17}$$

where θ captures the sensitivity of loan demand to the lending rate and $R_{E,t+1}$ is the expected return on capital.[10] Parameters θ and $R_{E,\star}$ are endogenously determined in the steady state, while $\bar{k}$ is recovered residually from the steady-state capital return condition using the aggregate loan supply.

Intuitively, higher asset returns increase the incentive to invest, raising the demand for loans. Under the logistic specification, loan demand becomes less sensitive to loan rates when lending rates are already high. Because the aggregate loan supply is tied to the asset price, a contraction in loan supply reduces the asset price and shifts loan demand upward, partially offsetting the initial decline.

The remaining parameters are calibrated directly from macro-financial data. The aggregate

[10] This representation of loan demand is similar to those in Wang et al. (2022) and Jiang (2023), with the difference that the return on capital is aggregate rather than idiosyncratic. A similar form can be obtained under linear utility with a GEV shock.

risk-free rate is set to the average effective federal funds rate between 2002 and 2023, excluding observations below 20 basis points per year. The recovery rate on assets is set to $\gamma = 0.65$, slightly higher than the 51–55% range reported by Correia et al. (2023), but consistent with Corbae and D'Erasmo (2021). The capital requirement ratio is fixed at $\kappa = 0.06$, matching the average Tier 1 capital ratio. The capital share α is set to 0.35, following standard values in the macro-finance literature, and the depreciation rate $\delta = 0.05$ implies an average loan maturity of five years.[11] The coupon rate c is set to zero. Table 2 summarizes the externally calibrated parameters.

Table 2: Fixed Parameters

Parameter	**Symbol / Value**	**Source / Target**
Capital share	$\alpha = 0.35$	Standard in literature
Depreciation rate	$\delta = 0.050$	Implies average loan maturity of 5 years
Risk-free rate (quarterly)	$R_f = 1.006$	Avg. Fed Funds rate (2001–2025)
Recovery rate on assets	$\gamma = 0.65$	Corbae and D'Erasmo (2021)
Capital requirement ratio	$\kappa = 0.06$	Tier 1 capital ratio
Time deposit maturity	$\lambda = 1/4$	One-year maturity
μ_z	-8×10^{-4}	Mean of Net-loan losses
ρ_Z	0.499	Persistence of Net-loan losses
η_z	0.001	Std dev. of Net-loan losses

Notes: Parameters in this table are externally fixed prior to the simulated method of moments (SMM) estimation. One model period corresponds to a quarter.

Targeted Moments

In this subsection, I assess whether the model can accurately approximate the targeted and untargeted moments. I begin by describing the endogenously calibrated parameters in the steady state, then discuss the targeted moments and their mapping to key bank frictions, and finally evaluate the model's fit and external validity.

Table 3 reports the parameters calibrated within the model. Because competition across banks is non-existent, the parameter governing the interest rate sensitivity of loan demand, θ, is higher than the value estimated by Wang et al. (2022). The steady-state entrepreneurial

[11] Geelen et al. (2024) document that debt maturity is positively correlated with asset life, as firms tend to match the maturity of assets and liabilities.

Table 3: Targeted Parameters

Parameter	Description	Calibrated Value
θ	Interest rate sensitivity	251
$\eta\omega$	Std. dev. of iid shock	0.025
ϕ	Constant scale of iid shock	0.10
σ	Manager myopia	0.98
ζ	Deposit cost	15×10^{-4}
ρ_R	Credit risk sensitivity	0.35
$R_{E,\star}$	Steady-state entrepreneurial return	1.085

Note: Parameters are calibrated to match the empirical moments reported in Table 4. $R_{E,\star}$ denotes the steady-state equilibrium return on equity, and c corresponds to the coupon rate on time deposits. All parameters are expressed in quarterly terms unless otherwise noted.

return, $R_{E,\star}$, plays a key role in matching the net interest margin, as it determines the level of the average lending rate. The myopia parameter, σ, is close to the value in Corbae and D'Erasmo (2021), which helps generate leverage ratios consistent with those observed in the data. The parameters that govern default behavior, ϕ and η_ω, are identified jointly in the calibration. Finally, the issuance cost of deposits, ζ, governs the equilibrium share of time deposits in total funding.

The targeted moments are chosen to reflect the key frictions that banks face in the model. Because banks operate in imperfectly competitive markets, their lending rates depend on the elasticity of loan demand. To capture this relationship, I target the empirical net interest margin (NIM), defined as the difference between interest income and interest expense divided by total assets. This moment summarizes banks' average markup over funding costs and disciplines the parameter θ, which governs the sensitivity of loan demand to interest rate changes—particularly when banks adjust their funding composition toward more costly time deposits.

A second key friction arises from the banks' exposure to default risk. While insured deposits are protected by the FDIC, time deposits are not, and thus carry an endogenous default premium. I measure this premium as the spread between rates on time deposits and savings

Table 4: Targeted Moments: Data vs. Model

Moment	**Data (%)**		**Model (%)**	
	Mean	Std. Dev.	Mean	Std. Dev.
Share of failing banks	0.14	—	0.15	—
Leverage	89.53	—	88.29	—
Share of time deposits	36.70	15.88	34.79	9.06
Net interest margin	0.89	—	0.99	—
Spread btwn. time dep. and deposit	0.37	—	0.17	—

Note: Empirical moments are computed from FFIEC Call Reports (2001–2025). Model moments correspond to the stationary equilibrium of the calibrated economy. All variables are expressed as percentages. Standard deviations are in percentage points.

and checking accounts, which serves as a moment capturing the equilibrium default risk in the model. Additionally, the observed failure rate of banks provides an aggregate indicator of default risk and is included among the targets.

The final set of moments captures banks' funding and leverage decisions. Banks can finance themselves through retained earnings or external liabilities, subject to regulatory and market constraints. I therefore target the average leverage ratio, which provide information about the tightness of these constraints. To discipline the model's funding structure, I target the mean and dispersion of the share of time deposits in total liabilities, which reflects banks' composition between iliquid and liquid funding.

Table 4 compares the model-implied and empirical moments. Overall, the model fits the data well. It closely matches the margins observed in the data and reproduces both the average leverage ratio and its volatility. The spread between time and core deposit rates is slightly smaller in the model—about 20 basis points below the data—consistent with the presence of liquidity premiums in deposits. The share of time-deposit funding and its standard deviation are also well captured, indicating that the model successfully reproduces heterogeneity in banks' funding composition.

The model's ability to match both the average leverage, funding composition, and pricing spreads supports its quantitative relevance. In the next subsection, I evaluate the model's

untargeted moments, which provide an additional validation of its capacity to capture banks' dynamic responses to shocks.

Untargeted Moments - Dynamics Around Default

The analysis of untargeted moments provides a complementary validation of the model's performance beyond the steady-state calibration. While the targeted moments ensure that the model matches key cross-sectional averages, the untargeted moments assess whether it can replicate the dynamic patterns observed in the data as banks approach default. In particular, I examine how leverage, profitability, and funding composition evolve in the simulated economy around episodes of bank failure. These dynamics are then compared to the empirical event-study patterns documented in Section 2, providing a test of whether the model captures the buildup of fragility that precedes default.

Leverage Dynamics. Figure 5 compares the evolution of leverage ratios in the data and in the simulated model around episodes of bank failure. Both series display a gradual and persistent increase in leverage in the years preceding default, reflecting the buildup of balance-sheet risk as banks accumulate liabilities relative to assets. The model closely tracks the empirical pattern, reproducing both the slow upward drift and the acceleration in leverage in the final quarters before failure. This close alignment suggests that the mechanisms governing funding decisions and default in the model successfully capture the gradual deterioration in banks' solvency observed in the data.

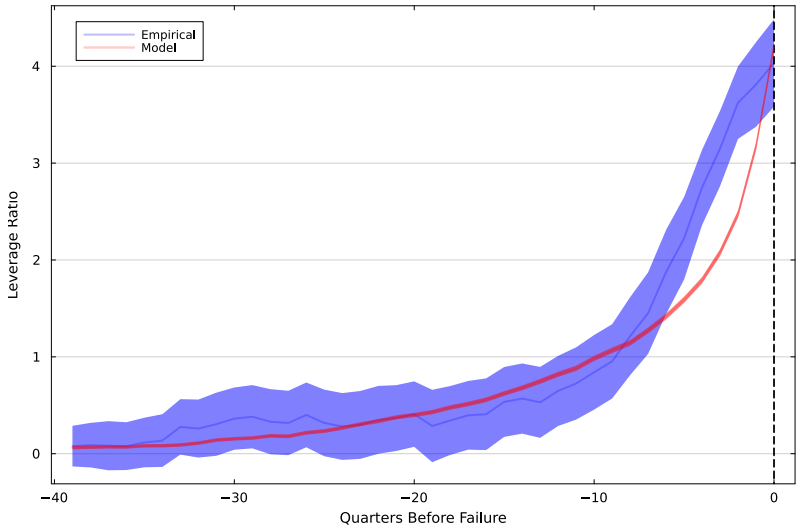

Figure 5: Leverage (Total Liabilities/Total Assets) Before Bank Failure

Funding Dynamics. Figure 6 compares the evolution of time deposits, expressed as a share of total liabilities, in the data and in the simulated model around episodes of bank failure. Both series show a gradual and sustained increase in the share of time deposits as default approaches, indicating that banks progressively shift toward illiquid and higher-yield funding sources when facing distress. The model captures both the timing and sign of this buildup, mirroring the empirical pattern. This alignment suggests that the mechanisms linking funding costs, funding choice, and solvency in the model successfully approximates the compositional changes in liabilities observed prior to failure.

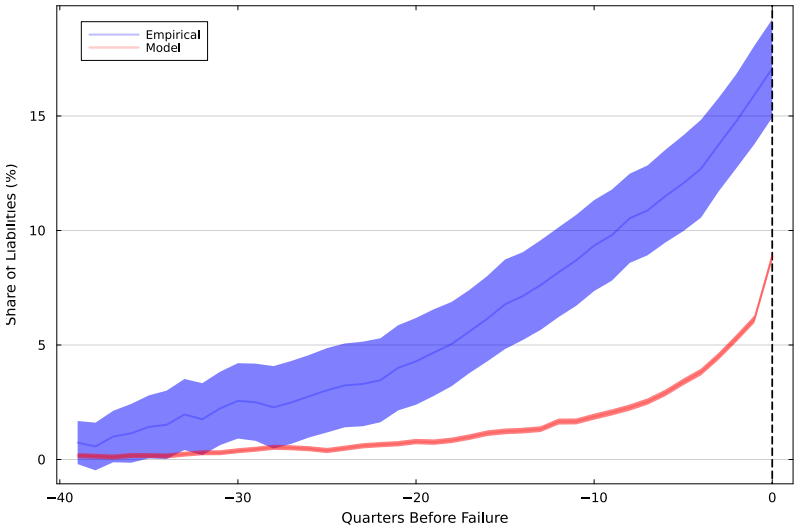

Figure 6: Time Deposits as a Share of Total Liabilities Before Bank Failure

Profitability Dynamics. Figure 7 compares the evolution of the net interest margin (NIM) in the data and in the simulated model around episodes of bank failure. Both series display a pronounced and sudden decline in NIM beginning roughly ten quarters before default, reflecting a sharp compression of lending margins as funding costs rise and profitability deteriorates. The model replicates this pattern, but overshoots the timing and intensity of the drop observed in the data. This sharp contraction in margins highlights how, late in the distress cycle, rising deposit rates and greater reliance on costly time deposits erode banks' profitability, ultimately precipitating default.

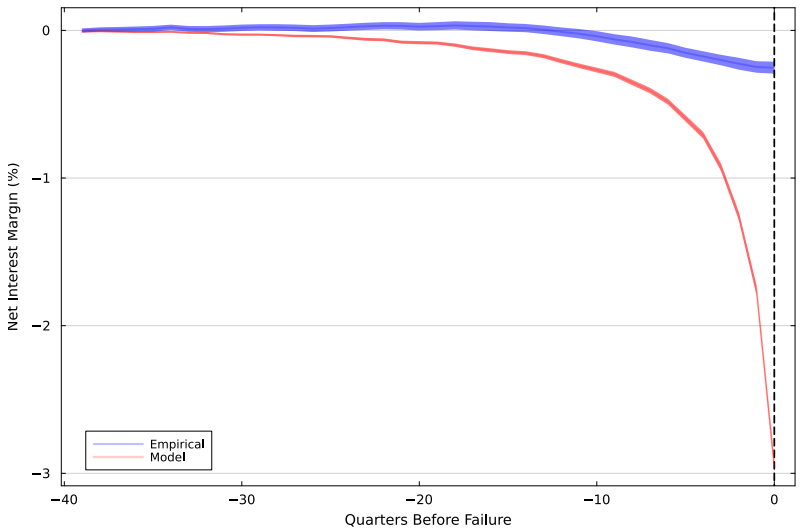

Figure 7: Net Interest Margin Before Bank Failure

Credit Losses. Figure 8 compares the evolution of net charge-offs in the data and in the simulated model around bank failures. Both series show a noticeable increase in charge-offs beginning roughly fifteen quarters before default, indicating a progressive deterioration in loan performance as banks approach distress. The model successfully reproduces the timing and trajectory of this increase, but the model was calibrated to match the average loan losses on default. This pattern reflects the buildup of credit risk that accompanies the funding and profitability pressures documented above: as margins compress and leverage rises, weaker balance sheets amplify exposure to loan defaults, eventually triggering bank failure.

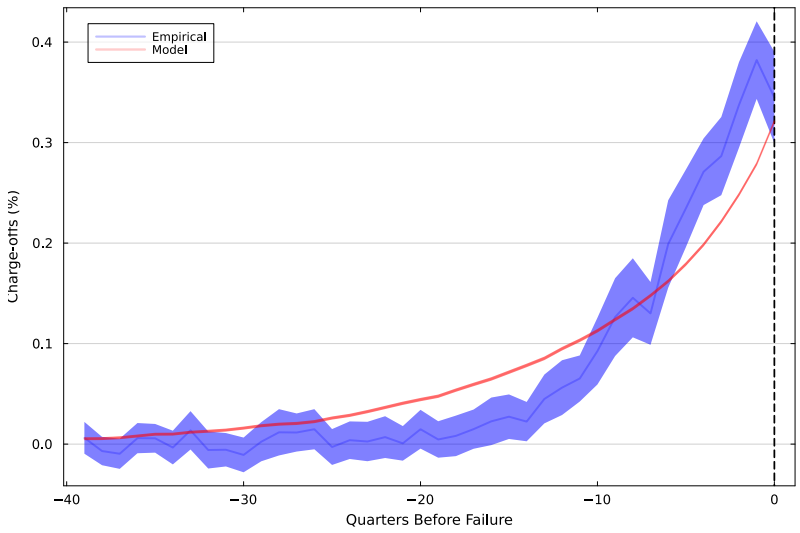

Figure 8: Net Charge-Offs Before Bank Failure

These untargeted moments show that the model successfully reproduces the sequence of deterioration that precedes bank failure. It captures the gradual buildup of leverage, the shift toward illiquid and costly funding, and the sharp compression in profitability that ultimately culminate in rising loan losses and default. Overall, these results indicate that the mechanisms governing funding, risk-taking, and solvency in the model provide a coherent quantitative account of the dynamics of financial distress in the banking sector.

Appendix C.3 examines how the interaction between optimal policy functions and the bank's value function along n and b accounts for the model's empirical patterns.

Variance Decomposition of Default

To connect the model most directly to the predictability patterns documented by Correia et al. (2023), I begin with a restricted variance decomposition that mirrors the information set in their empirical analysis. In particular, I regress the expected default probability on the two funding variables available in their setting—the share of time deposits and leverage—and compute their contributions using a two-variable *Shapley-value* decomposition. With only two regressors, each variable's contribution corresponds to the average of its marginal explanatory power when entering the prediction model first versus second, yielding an internally consistent and order-invariant allocation of the variance they jointly explain.

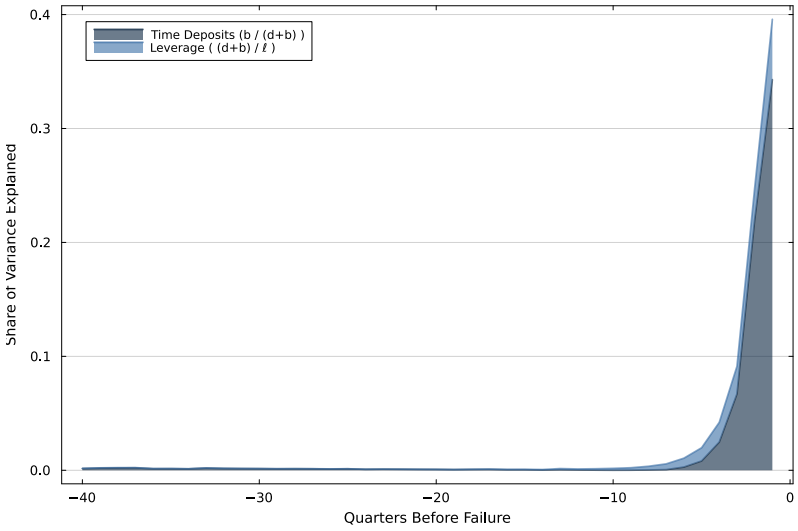

Figure 9: Restricted variance decomposition using leverage and time deposits.

Figure 9 displays the resulting decomposition over the forty quarters preceding failure. Consistent with the evidence in Correia et al. (2023), both time deposits and leverage explain very little of the cross-sectional variation in expected default far from failure, reflecting the relative homogeneity of solvent banks. Their explanatory power rises significantly only as failure approaches, indicating that funding structure becomes increasingly informative about distress as balance sheets deteriorate. Leverage captures the late-cycle surge in indebtedness, while the rise in time deposits reflects banks' shift toward more illiquid funding as cash flow pressures mount.

Having established the model's ability to replicate the empirical predictability patterns based solely on funding structure, I next turn to the full decomposition that includes loan losses. This richer specification regresses the expected default probability on the share of time deposits, leverage, and loan losses, and computes their contributions using the full Shapley-value approach. Each variable's contribution is the average of its marginal explanatory power across all possible orders in which the three regressors can enter the model, ensuring an order-invariant breakdown of the total explained variance.

Figure 10 reports the full decomposition. Early in the event window, all components explain less than 1% of the cross-sectional variation in expected default, consistent with the uniform stability of solvent banks. As failure approaches, however, loan losses emerge as the

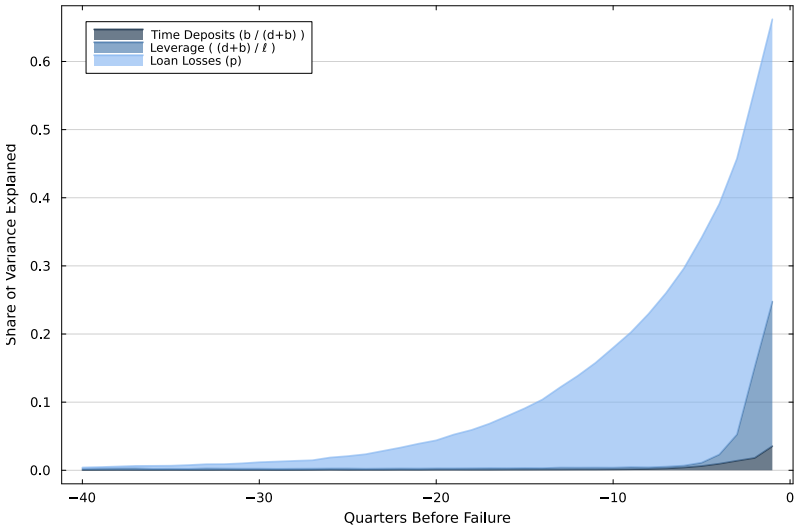

Figure 10: Full variance decomposition of expected default probability.

dominant driver: their contribution rises sharply over the final twenty quarters and accounts for the majority of the variation in expected default at the point of collapse. Leverage contributes modestly and only near failure, while the share of time deposits plays a smaller but meaningful role in shaping the slow-moving buildup of fragility.

To further interpret these mechanisms through the lens of the model, Appendix C.2 presents an analogous decomposition based on the deeper structural state variables—cash-on-hand n and the liquidity shock ω—which clarifies how liquidity conditions feed into the buildup of fragility. Unsurprisingly, this liquidity-management margin emerges as the main driver of subsequent fragility, and it is strongly correlated with banks' funding choices.

The restricted and full decompositions provide a compelling picture: funding structure contains substantial predictive power for future bank distress, especially in the quarters immediately preceding collapse, while the sharp rise in expected default risk is ultimately driven by deteriorating asset quality. The model therefore captures both the slow-moving buildup of vulnerability from funding choices and the rapid acceleration in risk associated with worsening fundamentals.

The Aggregate Implications of Time Deposits

To further understand the mechanism behind these choices, I consider a counterfactual economy in which banks cannot issue time deposits. Removing this funding instrument doubles the share of failing banks (from 0.15% to 0.30%) and induces banks to deleverage, reducing average leverage from 89.5% to 86.4%. Aggregate lending contracts modestly. These effects reflect heightened rollover risk: without access to long-maturity liabilities, banks become more sensitive to liquidity shocks and respond by shrinking their leverage. Appendix C.4 reports the full set of moments and dynamic event-study evidence.

The Effects of Capital Regulation

Table 5 reports steady-state moments for the benchmark economy and for a counterfactual economy with a higher Tier 1 capital requirement of 8 percent.

Increasing regulatory capital reduces banks' failure risk. The quarterly share of failing banks declines from 0.15 percent in the benchmark economy to 0.14 percent under the high-capital regime. Although this difference is small in any given quarter, it compounds over time. Over a 25-year horizon (100 quarters), the implied cumulative failure probability falls from roughly 15 percent to about 14 percent, corresponding to a reduction of approximately 1 percentage point. Importantly, this improvement in stability occurs without a meaningful change in average leverage, which declines only slightly—from 89.53 percent to 88.01 percent. Banks already maintain internal capital buffers in response to underlying credit and liquidity risk, so the higher regulatory minimum does not induce substantial deleveraging.

The tighter capital requirement also affects banks' funding choices. The average share of time deposits declines from 34.79 percent in the benchmark to 34.16 percent under higher capital requirements. In the model, banks rely on time deposits as a precautionary source of more stable, illiquid funding when rollover risk is elevated. Improved capitalization reduces the likelihood of entering the distress region, thereby lowering the incentive to rely on such precautionary funding. Consistent with this mechanism, the net interest margin declines modestly, from 0.99 percent to 0.98 percent.

Aggregate effects are modest. Lending increases slightly — from 12.30 to 12.31 model units —corresponding to an increase of about 0.13 percent. This increase reflects both the accumu-

lation of equity induced by tighter regulation, which allows banks to expand lending relative to their liabilities, and the reduced-form relationship between lending rates and credit risk, which leads to a more favorable distribution of credit.

Table 5: Targeted Moments: Benchmark Model and Higher Capital Requirement

Moment	**Benchmark (%)**	**Higher Capital (%)**
Share of failing banks	0.15	0.14
Leverage	89.53	88.01
Share of time deposits	34.79 (9.06)	34.16 (9.00)
Net interest margin	0.99	0.98
Spread between time dep. and deposits	0.17	0.17
Lending	12.30	12.31

Note: Standard deviations are shown in parentheses. Moments correspond to stationary equilibria of the benchmark economy and an economy with a Tier 1 capital requirement of 8 percent. Lending is reported in model units rather than percentages.

These muted effects are consistent with the variance-decomposition results from the previous section. The decomposition shows that most of the variation in expected default is driven by movements in loan charge-offs, particularly in the quarters immediately preceding failure. While leverage and maturity choice explain only a limited share of the variation when the bank gets closer to fail.

Raising regulatory capital increases banks' distance from the default boundary. However, because default risk in the model is ultimately driven by large credit losses—rather than by funding maturity or leverage dynamics—a moderate increase in required capital cannot fully offset the shocks that push banks into distress. As a result, higher capital reduces failure risk only gradually, even though it improves the overall resilience of bank balance sheets.

Overall, this counterfactual demonstrates that higher capital requirements primarily operate by strengthening banks' balance sheets and reducing their exposure to rollover risk, rather than by significantly altering leverage or lending activity. The adjustments across moments are modest, indicating that a moderate increase in regulatory capital ratios can enhance financial stability with limited effects on aggregate lending.

A related counterfactual, presented in Appendix C.6, explores the same increase in the Tier 1 capital requirement in a version of the model without time deposits. This experiment

delivers two additional insights. First, the reduction in failure risk is of a larger magnitude to the benchmark model, indicating that the stabilizing effect of higher capital does not rely on banks' ability to adjust the maturity composition of their funding. Second, aggregate lending rises in this version of the model, since improved bank survival expands the supply of credit. These results imply an unambiguous welfare improvement: the counterfactual model experiences fewer failures and more lending, similar to the result with time deposits.

Dilution Premium

In this section, I study an alternative to capital regulation in which banks must pay a premium—implemented as a debt covenant—when issuing time deposits. This premium offsets debt dilution by forcing banks to internalize the dilution costs imposed on outstanding long-term liabilities.

I formalize this mechanism by introducing a debt covenant in the spirit of Hatchondo et al. (2016). The covenant specifies that whenever a bank issues new time deposits, it must compensate existing time-deposit holders by paying the difference between the counterfactual bond price that would prevail in the absence of outstanding long-term debt, $q_b(z, R_\ell, d', 0)$, and the observed time-deposit price, $q_b(z, R_\ell, d', b')$.

Formally, the total covenant payment associated with the issuance of new time deposits is given by

$$CP(z, R_\ell, d', b') = b(1-\lambda)[q_b(z, R_\ell, d', 0) - q_b(z, R_\ell, d', b')],$$

where $b(1-\lambda)$ denotes the stock of previously issued time deposits that remain outstanding.

This covenant effectively requires banks to buy back all outstanding time deposits at the counterfactual no-dilution price when issuing new debt. As a result, banks cannot dilute the value of existing long-term liabilities through additional issuance, and debt dilution is eliminated by construction.

The covenant modifies the bank's issuance problem by making the cost of issuing time deposits depend on the induced change in the market value of outstanding liabilities. In doing so, the bank internalizes the effect of current issuance on previously issued long-term debt, eliminating incentives to issue new liabilities at the expense of existing debt holders.

Under the covenant, the bank's dividend is reduced by a transfer to existing time-deposit holders whenever new time deposits are issued. This transfer equals the outstanding stock of time deposits multiplied by the difference between the no-dilution price and the observed issuance price, and it enters the dividend as an additional issuance cost:

$$\text{div} = n - \ell^d(R_\ell, R'_E) + q_d\, d' + q_b(z, R_\ell, d', b')\big(b' - (1-\lambda)b\big) - Z(d') - CP(z, R_\ell, d', b') \geq 0.$$

I refer to this environment as the *dilution-premium economy* and compare it to the benchmark economy.

From a policy perspective, this covenant can be interpreted as a regulatory or contractual mechanism that targets issuance incentives rather than balance-sheet quantities. Unlike capital or liquidity requirements, which restrict leverage or funding composition ex post, the dilution premium operates at the margin of issuance by forcing banks to internalize the effect of new long-term debt on the value of existing liabilities. In practice, such a mechanism could be implemented through supervisory approval requirements for long-term deposit issuance, issuance fees that depend on outstanding maturity structure, or contractual clauses that protect incumbent creditors from dilution. The objective is not to restrict access to long-term funding, but to align private issuance incentives with the social cost of dilution.

Table 6 compares stationary moments in the benchmark economy and in the dilution-premium economy. Introducing the dilution premium leads banks to substantially reduce their reliance on time deposits: the average share of time deposits falls from 34.8 percent to 19.2 percent, and the spread between time deposits and deposits collapses to zero. These changes reflect that, under the covenant, banks internalize the impact of new issuance on the value of outstanding long-term liabilities, eliminating incentives to dilute existing debt holders in favor of equity holders.

As a consequence, banks have weaker incentives to operate at high leverage, which is associated with a modest decline in the share of failing banks. Despite these balance-sheet adjustments, aggregate lending is unchanged, indicating that the covenant primarily alters the composition of bank funding rather than the overall scale of lending.

Lastly, to understand how this policy affects the dynamics around bank failures, I conduct the same model-based event study as the benchmark model.

Table 6: Targeted Moments: Benchmark and Dilution Models

Moment	**Benchmark (%)**	**Dilution Premium (%)**
Share of failing banks	0.15	0.13
Leverage	89.53	85.41
Share of time deposits	34.79 (9.06)	19.18 (8.00)
Net interest margin	0.99	1.06
Spread between time dep. and deposits	0.17	0.00
Lending	12.30	12.30

Note: Standard deviations are shown in parentheses. Moments correspond to stationary equilibria of the benchmark economy and the dilution premium economy. Lending is reported in model units rather than percentages.

Leverage Dynamics. Figure 11 compares the evolution of leverage ratios in the data and in the simulated model around episodes of bank failure. In the data, leverage rises steadily in the years preceding default, reflecting the gradual buildup of balance-sheet risk as liabilities grow relative to assets.

In contrast, in the dilution-premium economy leverage declines as banks approach default. By forcing banks to internalize the dilution costs imposed on outstanding long-term liabilities, the covenant weakens incentives to expand balance sheets through debt issuance in distress. As a result, banks enter failure episodes with lower leverage, even as funding conditions deteriorate.

This divergence highlights the role of debt dilution in driving leverage cycles prior to default: when dilution incentives are removed, banks respond to distress by deleveraging rather than by expanding liabilities.

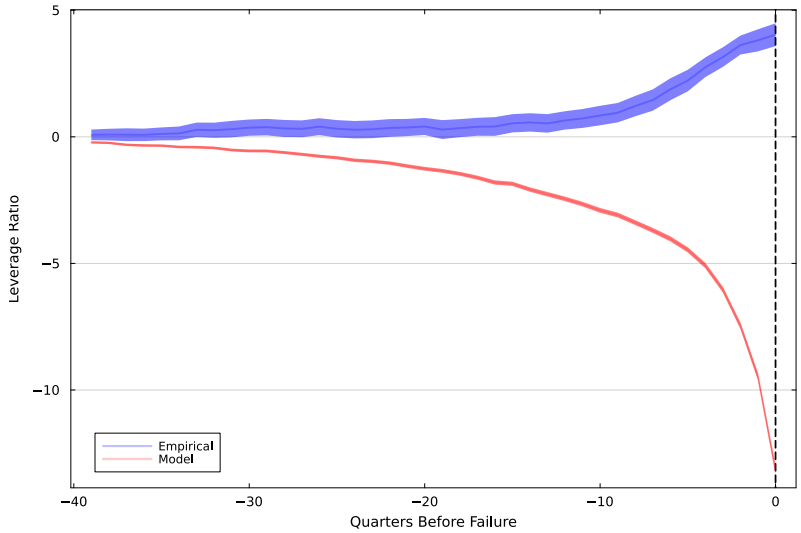

Figure 11: Leverage (Total Liabilities/Total Assets) Before Bank Failure

Funding Dynamics. Figure C.12 in the Appendix compares the evolution of time deposits, expressed as a share of total liabilities, in the data and in the simulated model around episodes of bank failure. In both cases, the share of time deposits increases gradually as default approaches, indicating that banks progressively shift toward illiquid and higher-yield funding sources when facing distress.

The model reproduces the timing of this buildup closely but generates a somewhat larger increase in the time-deposit share than the benchmark model. This amplified shift reflects the model's mechanism: by eliminating debt dilution, the covenant weakens incentives to expand balance sheets through leverage, leading banks to adjust primarily along the composition margin. As a result, funding stress manifests more strongly through changes in liability composition rather than through increases in total leverage.

Despite this amplification, the model captures the qualitative pattern observed in the data, highlighting the central role of funding composition in the run-up to bank failure.

Profitability Dynamics. Figure C.13 in the Appendix illustrates the evolution of the net interest margin (NIM) in the dilution-premium economy around bank failure episodes. In the early stages of distress, profitability remains relatively stable, reflecting that the covenant dampens increases in effective funding costs. By forcing banks to internalize dilution costs at

issuance, the premium weakens incentives to expand liabilities aggressively, limiting upward pressure on deposit rates and supporting net interest margins.

As banks approach default, however, this stabilizing effect fades. Beginning roughly four quarters before failure, NIM declines sharply as funding conditions deteriorate and credit losses accumulate. In the late stages of distress, rising deposit rates, increased reliance on costly time deposits, and mounting loan losses compress margins sufficiently to generate net losses, ultimately precipitating default.

This pattern highlights that while the dilution premium dampens funding-cost issues early in the failure cycle, it does not insulate banks from persistent deterioration of fundamentals.

Credit Losses. Figure C.14 in the Appendix compares the evolution of net charge-offs in the benchmark model and in the dilution-premium economy around bank failure episodes. Relative to the benchmark, credit losses begin to rise earlier in the dilution-premium economy, reflecting a more front-loaded deterioration in loan performance. This pattern indicates that, by weakening incentives to deleverage through liability expansion, the dilution premium allows banks to operate for longer despite worsening credit conditions.

These results show that imposing a debt dilution premium fundamentally alters how banks respond as they approach failure. Under the dilution premium, banks deleverage as default approaches, rely more heavily on time deposits, and experience a delayed but ultimately sharp decline in profitability. Credit losses remain an important driver of default in both environments, but in the dilution-premium economy losses begin to rise earlier, while banks continue to operate through balance-sheet adjustment rather than leverage expansion.

Overall, the covenant reduces leverage cycles prior to failure while leaving aggregate lending largely unchanged, highlighting the role of debt dilution in shaping banks' funding choices and their resilience to distress.

In sum, the dilution premium alters banks' responses to distress by eliminating incentives to dilute outstanding long-term liabilities. Banks deleverage rather than expand balance sheets as fundamentals deteriorate, reducing leverage cycles prior to default while preserving aggregate lending. This highlights debt dilution as a central driver of pre-failure dynamics.

5. Conclusion

This paper develops and quantifies a model of bank failures that links funding maturity and debt dilution to the gradual buildup of fragility observed in U.S. commercial banks. Empirically, banks approaching failure systematically reshape their liability structure: they increase reliance on time deposits, experience rising funding costs, and display deteriorating profitability, leverage, and loan performance. These patterns indicate that liability composition is not merely a passive reflection of distress, but an active margin through which banks manage rollover risk—while simultaneously shaping incentives that affect the timing and severity of default.

Motivated by these facts, I build a dynamic model in which heterogeneous banks choose between short- and long-maturity liabilities under limited commitment and capital requirements. Time deposits reduce rollover risk and smooth liquidity needs, allowing banks to avoid forced deleveraging early in distress episodes. At the same time, because equity can only be rebuilt through retained earnings, long-maturity funding creates incentives to dilute outstanding creditors through additional issuance. As fundamentals deteriorate, this debt-dilution channel relaxes short-run balance-sheet constraints at the cost of increasing future repayment obligations, amplifying leverage and accelerating the transition toward default. The model generates endogenous default and reproduces the key pre-failure dynamics documented in the data, including rising leverage, increasing reliance on time deposits, compressing net interest margins, and escalating charge-offs.

The counterfactual exercises isolate the distinct roles of funding maturity, capital constraints, and dilution incentives. Removing access to time deposits forces banks to hedge rollover risk through early deleveraging, reducing leverage but increasing failure rates as exposure to liquidity shocks rises. Tightening capital requirements limits leverage mechanically and improves resilience, yet leaves banks' incentives to dilute long-term creditors largely unchanged. In contrast, imposing a dilution premium that forces banks to internalize the effect of new issuance on the value of outstanding time deposits eliminates dilution incentives while preserving the liquidity benefits of long-maturity funding. This incentive-targeting intervention substantially changes leverage cycles prior to default and alters failure dynamics without materially affecting aggregate lending.

Overall, the analysis shows that bank fragility is shaped not only by asset-side risk or regulatory constraints, but by liability-side incentives that evolve endogenously over the distress cycle. Long-maturity funding can stabilize banks early on by reducing rollover risk, yet—absent mechanisms that internalize dilution—it becomes a source of amplification as profitability weakens and equity rebuilds slowly. By endogenizing funding structure, leverage, default, and dilution incentives, the paper provides a framework for understanding why bank distress emerges gradually and for evaluating regulatory approaches that target incentives rather than balance-sheet quantities alone.

A. Empirical Appendix

A.1. Data Sources

Call Reports and Uniform Bank Performance Reports Data from the Call Reports are obtained from the Uniform Bank Performance Reports (UBPR), supplied by the FFIEC, covering the years 2001 to 2025. The Call Reports include all FDIC-insured commercial banks, savings banks, and savings associations. The dataset compiles quarterly reports from each insured institution and constructs standardized measures for a wide range of bank-specific ratios. All variable definitions follow the UBPR documentation.

All ratios are trimmed if they lie more than three standard deviations above the sample mean. Additionally, I winsorize all variables at the 2.5th and 97.5th percentiles.

Variable Definitions

Bank Leverage. Leverage is defined as the ratio of total liabilities (**RCON2948**) to total assets (**RCON2170**).

Net Interest Margin.

$$\text{NIM}_{j,t} = 100 \times \frac{RIAD4107_{j,t} - RIAD4073_{j,t}}{RCON3368_{j,t}}$$

where interest income (**RIAD4107**) and interest expense (**RIAD4073**) are expressed as quarterly flows and divided by the quarterly average of total assets (**RCON3368**).

Net Income Margin.

$$\text{Net Income Margin}_{j,t} = 100 \times \frac{RIAD4340_{j,t}}{RCON3368_{j,t}}$$

where net income (**RIAD4340**) is expressed as a quarterly flow and divided by the quarterly average of total assets (**RCON3368**).

Net Charge-offs.

$$\text{nco}_{j,t} = 100 \times \frac{RIAD4635_{j,t} - RIAD4605_{j,t}}{RCON3360_{j,t} + RCON3484_{j,t}}$$

where charge-offs on loans and leases (**RIAD4635**) and recoveries (**RIAD4605**) are expressed as quarterly flows and divided by the quarterly average of loans and leases (**RCON3360** plus **RCON3484**).

Interest Rate on Savings And Checking Accounts. The Savings And Checking Accounts deposit interest rate $\text{IntSavCheck}_{j,t}$ is computed as:

$$\text{IntSavCheck}_{j,t} = 100 \times \frac{(\text{RIAD4508}_{j,t} + \text{RIAD0093}_{j,t})}{\text{RCONB563}_{j,t} + \text{RCON3485}_{j,t}},$$

where RIAD4508 $\text{RIAD0093}_{j,t}$ denotes the quarterly flow obtained by differencing year-to-date interest expenses within each bank-year. Thus, the numerator captures interest paid on savings and checking deposits, while the denominator reflects the contemporaneous stock of savings and checking deposits.

Interest Rate on Time Deposits. The variable $\text{TD rate}_{j,t}$ is constructed according to the FFIEC reporting change effective in 2018:

$$\text{TD rate}_{j,t} = 100 \times \begin{cases} \dfrac{\text{RIADHK03}_{j,t} + \text{RIADHK04}_{j,t}}{\text{RCONHK16}_{j,t} + \text{RCONHK17}_{j,t}}, & \text{if reporting date} > \text{2017-01-01}, \\ \dfrac{\text{RIADA517}_{j,t} + \text{RIADA518}_{j,t}}{\text{RCONA514}_{j,t} + \text{RCONA529}_{j,t}}, & \text{otherwise.} \end{cases}$$

where every interest expense is expressed as quarterly flows.

Time Deposits Below and Above the Insurance Limit. The stocks of time deposits below and above the FDIC insurance limit are defined according to the FFIEC reporting

change effective in 2018:

$$\mathrm{TD}_{j,t}^{\mathrm{below}} = \begin{cases} \mathrm{RCONHK16}_{j,t}, & \text{if reporting date} > \text{2017-01-01}, \\ \mathrm{RCONA529}_{j,t}, & \text{otherwise}, \end{cases}$$

$$\mathrm{TD}_{j,t}^{\mathrm{above}} = \begin{cases} \mathrm{RCONHK17}_{j,t}, & \text{if reporting date} > \text{2017-01-01}, \\ \mathrm{RCONA514}_{j,t}, & \text{otherwise}. \end{cases}$$

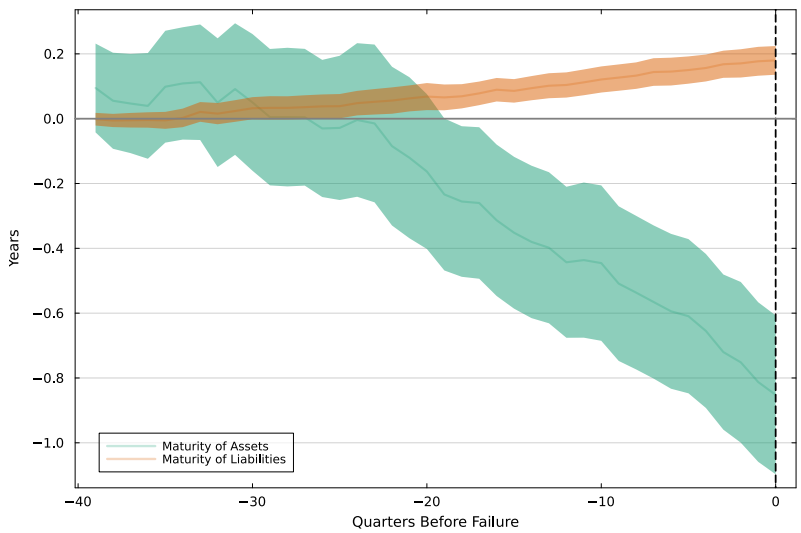

Figure A.1: Maturity of Assets and Liabilities Before Bank Failure

B. Model Appendix

Exit and Entry

Exit from the market is endogenous and depends on the bank's default decision. In each period, the mass of entering banks, μ_e, equals the mass of exiting banks. Each entrant is endowed with initial equity $\bar{n}$ and begins operation with zero debt.

New banks inherit the pool of entrepreneurs previously served by exiting banks, thereby preserving the distribution of idiosyncratic shocks in the economy. This assumption captures the idea that entrants fill the market positions vacated by failed banks, maintaining a stable environment.

Monetary Authority

The final component of the model is the monetary authority, which determines the real interest rate.

Monetary Authority. The monetary authority sets the real risk-free rate $R_{f,t}$ according to:

$$\log(R_{f,t}) = -\log(\beta), \tag{A.1}$$

implying a constant steady-state real rate consistent with the household's intertemporal discount factor.

Equilibrium

I now define the competitive equilibrium in the steady state.

Law of Motion for the Distribution of Banks. Before defining the equilibrium, I first characterize the evolution of the bank distribution in steady state, with an analogous structure during the transition.

Let the optimal policies conditional on states (z, n, b) be:

$$R_\ell^\star(z, n, b), \quad d^{\star\prime}(z, n, b), \quad b^{\star\prime}(z, n, b),$$

where $R_\ell^\star(z, n, b)$ is the optimal lending rate, $d^{\star\prime}(z, n, b)$ the optimal deposit issuance, and $b^{\star\prime}(z, n, b)$ the optimal long-term liability policy.

These policies may be empty when the non-negative dividend constraint is violated, in which case the bank defaults. Upon default, a new bank enters the economy with initial equity $\bar{n}$, no long-term liabilities, and inherits the exiting bank's client pool, characterized by the same p. In equilibrium, the mass of entrants equals the mass of defaulting banks, maintaining a constant measure of active banks over time.

Let μ denote the cross-sectional distribution of banks over (z, n, b). The mass of exiting (defaulting) banks is given by:

$$\mu^e = \int h^\star(z, n, b)\, d\mu(z, n, b),$$

where $\delta^\star$ is the bank's default policy.

Define the law of motion for net worth as:

$$n'(z', \omega', p, n, b) = n'(z', \omega', R_\ell^\star(z, n, b), d^{\star\prime}(z, n, b), b^{\star\prime}(z, n, b)),$$

and let the indicator function for next-period states be:

$$\mathbb{I}(z', \omega', n', b' | p, n, b) = \begin{cases} 1, & \text{if } (z', \omega', n', b') = (z', \omega', n'(z', \omega', p, n, b), b^{\star\prime}(z, n, b)), \\ 0, & \text{otherwise.} \end{cases}$$

The distribution of incumbent banks evolves according to:

$$\mu_i'(z', n', b') = \int (1 - \delta^\star(z, n, b))\, \mathbb{I}(z', \omega', n', b' | p, n, b)\, G(\omega') F(z' \mid z)\, d\mu(z, n, b),$$

where $G(\omega')$ and $F(z' \mid p)$ are the transition probabilities of the exogenous shocks ω and p, respectively.

Similarly, the distribution of entrant banks evolves as:

$$\mu_e'(z', n', b') = \int \delta^\star(z, n, b)\, \mathbb{I}(z', \omega', n', b' | p, \bar{n}, 0)\, G(\omega') F(z' \mid p)\, d\mu(z, n, b).$$

Since entrants inherit the client pools of exiting banks, the entrant distribution depends on the same loan-performance state p.

The overall law of motion of the bank distribution is:

$$\mu'(z', n', b') = \mu_i'(z', n', b') + \mu_e'(z', n', b').$$

A stationary distribution satisfies:

$$\mu^\star(z, n, b) = \mu'(z, n, b) = \mu(z, n, b),$$

implying that the inflow and outflow of banks are balanced, and the cross-sectional distribution of banks remains constant over time.

Capital Market Clearing. Consider the distribution of operating banks $\mu(z, n, b)$. Let $R_\ell^\star(z, n, b)$ denote the optimal loan rate policy. Each bank's loan supply is given by $\ell^s(z, n, b) = \ell^d(R_\ell^\star(z, n, b), R_E')$.

Since banks may default, aggregate loan supply also accounts for new entrants:

$$L^s = \int [1 - \delta^\star(z,n,b)]\, \ell^s(z,n,b)\, d\mu(z,n,b) + \int \delta^\star(z,n,b)\, \ell^s(z,\bar{n},0)\, d\mu(z,n,b),$$

where the first term represents incumbent banks and the second represents entrants. Given the normalization of the capital price to one, market clearing in the capital market requires:

$$K' = L^s, \tag{A.2}$$

where K' denotes aggregate capital next period.

Definition 1. *A stationary competitive equilibrium consists of value functions $V(z,n,b)$; decision rules $R_\ell(z,n,b)$, $d'(z,n,b)$, $b'(z,n,b)$; a measure of banks $\mu(z,n,b)$; debt price schedules $q_d(z,R_\ell,d',b')$ and $q_b(z,R_\ell,d',b')$; a borrowing decision $\ell(R^j_\ell, R'_E)$; and a set of prices P such that:*

- *Entrepreneurs maximize expected utility given the loan rate R^j_t, consistent with their borrowing decision and utility function;*
- *Banks choose $R_\ell(z,n,b)$, $d'(z,n,b)$, and $b'(z,n,b)$ to maximize their value functions;*
- *Households price default risk competitively and optimize their portfolio decisions;*
- *Firms maximize profits given factor prices;*
- *The distribution of banks $\mu(z,n,b)$ is consistent with individual policy functions and the law of motion above;*
- *All markets clear.*

One of the key state variables of interest is the cross-sectional distribution of banks across (z,n,b).

C. Quantitative Appendix

C.1. Algorithm for Steady State

The bank problem is solved using value function iteration (VFI) due to the existence of two defaultable liabilities, which might cause indeterminacy. In the benchmark setup, I have

111, 201, and 151 grids for the endogenous choice variables, R_ℓ, d', and b', respectively. Additionally, I use 7 grid points for z, 101 for n, and 21 for ω. After each iteration, I update both liability prices to speed up the computational time, dampening the updates as the number of iterations increases. I stop the process if the distance between iterations is below a tolerance of 10^{-5}, due to the numerical precision of using single precision at the GPU. Then, I store the policies for each grid point of (z, n, b).

The algorithm to solve the steady-state mass of banks according to their variables (z, n, b) follows Young (2010). Since the number of grid points for the endogenous variables for the cash-on-hand (n) is significantly smaller than the number of grid points for R_ℓ, d', it generates a faster convergence speed than if I were to have (z, ℓ, d, b, ω) as state variables. Therefore, my vector for the steady state distribution is given by (z, n, b), which has more than 70 thousand grid points. Finally, I compute a transition matrix for (z, n, b), iterating with an initial guess for μ 5.000 times, which guarantees a convergence of the distribution.

C.2. Variance Decomposition

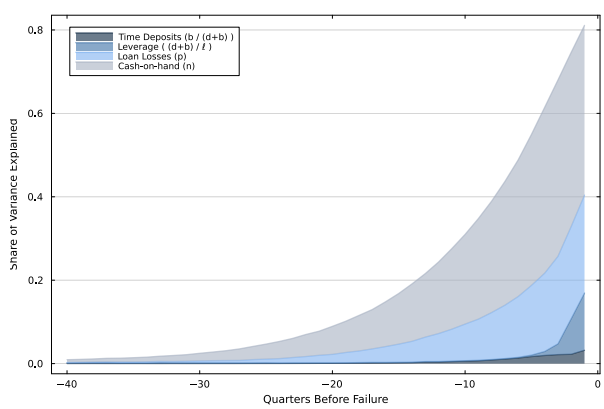

Figure C.1: Variance decomposition using leverage, time deposits, loan losses, and cash-on-hand

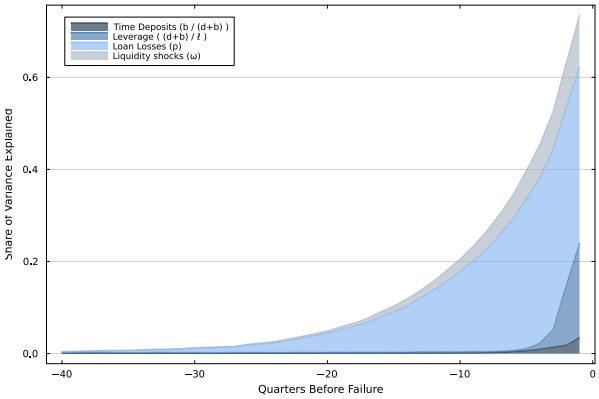

Figure C.2: Variance decomposition using leverage, time deposits, loan losses, and omega

C.3. Breaking down the mechanism

To understand how the model replicates the empirical patterns, I examine how the optimal policy functions interact with the bank's value function with respect to its liquidity position n and its outstanding stock of time deposits b. This decomposition illustrates how balance-sheet decisions respond to liquidity, default, and the maturity structure of liabilities.

Figure C.3 plots the optimal choice of time deposits as a share of total liabilities across the state space. The policy is monotone in the two state variables: the time-deposit share is increasing in the inherited stock of time deposits b and decreasing in cash-on-hand n. The bright band in the upper-left region corresponds to states with low liquidity and large outstanding time deposits—states close to default. In these distressed situations, banks optimally tilt their funding mix toward long-maturity liabilities, choosing time-deposit shares near one to lock in funding and reduce immediate rollover pressure.

As we move toward states with higher cash-on-hand or lower outstanding time deposits, the optimal time-deposit share declines smoothly. Banks that are far from default rely more heavily on short-term deposits, valuing the flexibility of short-maturity funding over the insurance provided by long-term liabilities. This pattern shows that the model concentrates long-maturity funding precisely where rollover risk is most severe.

To further understand why these patterns arise, Figure C.4 plots the optimal dividend payout. Dividend payments are sharply state-dependent and display a clear threshold structure. Banks near the default region—characterized by low liquidity n relative to outstanding time

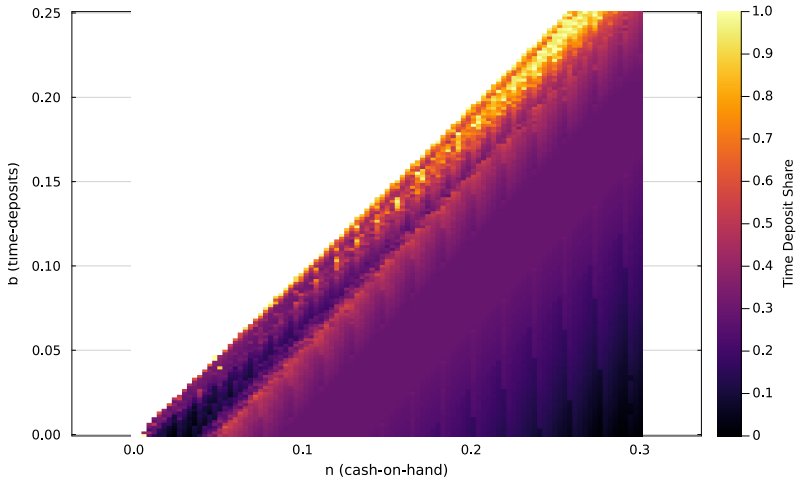

Figure C.3: Optimal share of time deposits across the state space at best z

deposits b—pay zero dividends, as preserving internal liquidity is more valuable than distributing resources to shareholders. This dark diagonal region aligns with the frontier where the bank is most at risk of violating its funding constraint.

Moving away from this boundary, dividend payouts increase smoothly. Banks with sufficient cash-on-hand relative to their time-deposit burden begin paying positive dividends, and the payout rises rapidly in states where liquidity is abundant. The bright region in the lower-right portion of the figure corresponds to banks that face minimal rollover risk. For these banks, the marginal value of internal funds is low, making dividend distribution the optimal use of excess resources.

The dividend and time-deposit policies trace out a coherent mechanism: near-default banks hoard liquidity and extend the maturity of their liabilities, while well-capitalized banks relax both margins—reducing long-term funding and distributing dividends more aggressively.

Lastly, to understand the mechanism behind the relaxation channel of time deposits, I examine how marginal changes in liquidity and outstanding time deposits affect the bank's continuation value. Specifically, I plot the derivatives of the value function with respect to n and b. These objects capture how valuable an additional unit of internal liquidity is, and how costly an additional unit of outstanding long-maturity liabilities becomes, across the

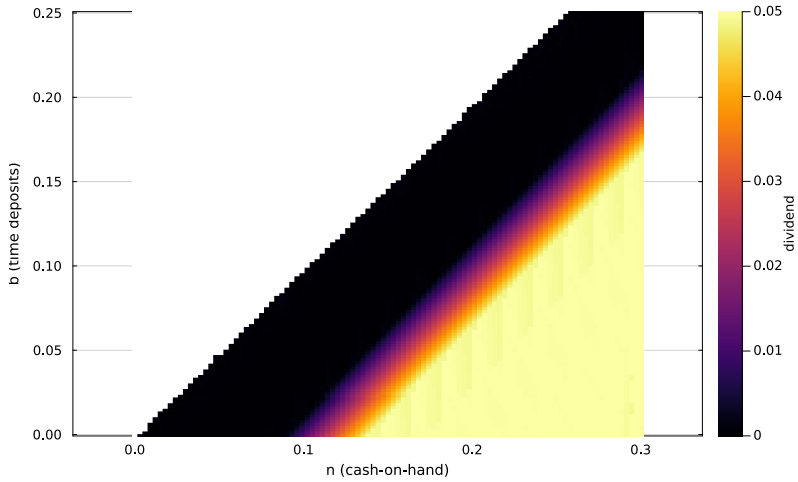

Figure C.4: Optimal dividend payout across the state space at best z

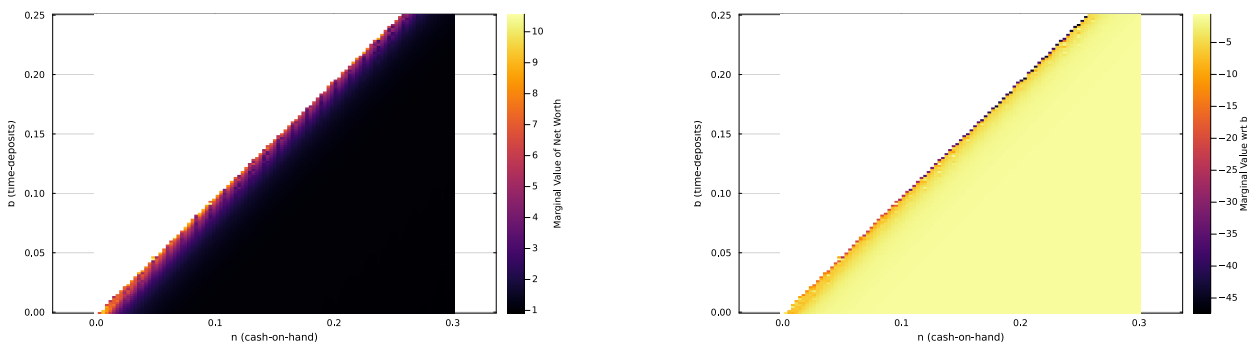
state space. Comparing $\partial V/\partial n$ and $\partial V/\partial b$ reveals why distressed banks hoard liquidity and increase their reliance on time deposits, while well-capitalized banks relax both margins.

Figure C.5 displays these derivatives at the highest productivity state z. The panels reveal a sharp asymmetry in how banks value liquidity versus long-term liabilities.

Panel (a) shows that $\partial V/\partial n$ is extremely high along the default frontier, where cash-on-hand is low relative to outstanding time deposits. In this distressed region, an additional unit of liquidity generates a steep increase in continuation value, reflecting the bank's urgent need to meet funding obligations and avoid insolvency. As n increases, the marginal value of liquidity declines rapidly, approaching zero for well-capitalized banks that are far from violating their funding constraint.

Panel (b) displays the opposite pattern for $\partial V/\partial b$. Near the default frontier, the marginal cost of additional time deposits is strongly negative: issuing more long-term liabilities sharply reduces continuation value because it tightens the funding constraint. As cash-on-hand rises, the marginal cost of time deposits becomes small in magnitude—approaching zero for banks with substantial cash buffers. In these regions, long-maturity liabilities are almost neutral for continuation value, as cash-flow risk is negligible.

Together, these gradients provide the key intuition for the model's mechanism. Distressed



(a) $\partial V/\partial n$ at best possible shock z

(b) $\partial V/\partial b$ at best possible shock z

Figure C.5: Derivatives of the value function with respect to liquidity and time deposits

banks face both a high marginal value of liquidity and a high marginal cost of additional long-term liabilities.[12] As a result, banks optimally hoard liquidity and adjust their liability composition to mitigate future rollover risk. Conversely, well-capitalized banks experience nearly flat marginal values along both dimensions, enabling them to reduce time-deposit issuance and distribute dividends more aggressively. These features of the value function generate the monotone policy patterns shown earlier.

To further understand the interaction between cash-on-hand and time deposits, Figure C.6 plots the cross-derivative of the value function with respect to cash-on-hand and time-deposits.

Positive values of the cross-derivative near the default frontier indicate that leverage amplifies the marginal value of liquidity in distressed states, while flatter regions away from default reflect weak interactions between liquidity and liability composition for well-capitalized banks. In particular, as banks approach default, an increase in time deposits raises the value of an additional unit of cash-on-hand, reflecting tighter funding constraints.

To conclude, Figure C.7 plots the inherited share of time deposits for the empirically relevant region of the state space, showing the combinations of (n, b) where the stationary distribution assigns significant probability mass. Two features stand out. First, banks rarely operate in

[12]Because these derivatives are computed on a coarse grid and correspond to economically distinct margins, their magnitudes should not be interpreted as directly comparable. Instead, they are used to characterize the local steepness of the value function along each dimension.

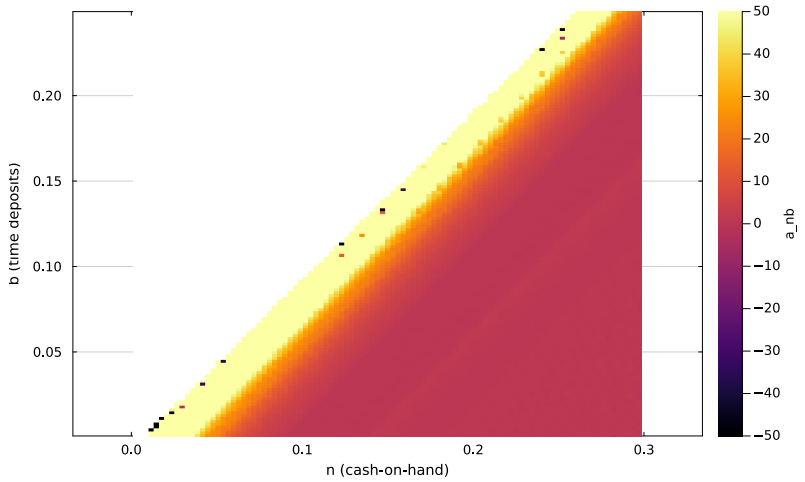


Figure C.6: Cross-derivative of the value function, $V_{nb} = \partial^2 V / \partial n \partial b$.

the distressed portion of the state space where the optimal policy implies time-deposit shares close to one; these high–time-deposit states lie close to the default frontier and are visited infrequently in equilibrium. Second, most banks cluster in a region with intermediate shares of time deposits, where liquidity is sufficient to avoid rollover risk but not so abundant as to make long-maturity funding redundant. This distributional pattern confirms the mechanism: the model endogenously pushes banks away from the extreme corner associated with rollover stress, resulting in a realistic mix of short- and long-maturity liabilities in steady state.

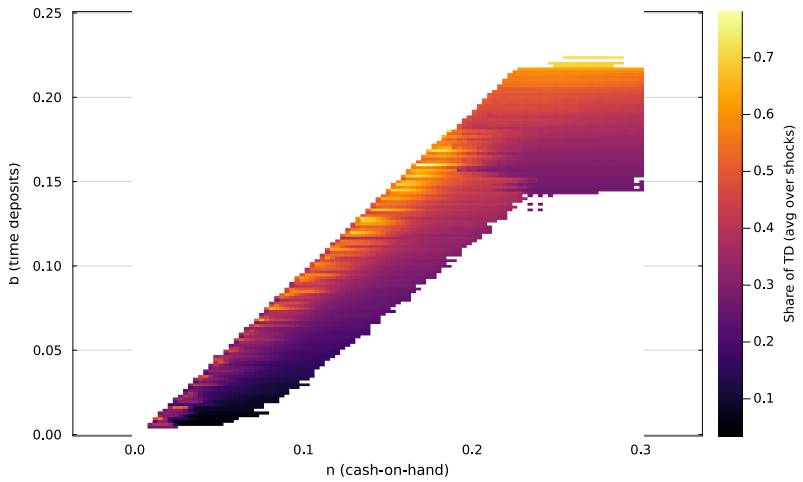

Figure C.7: Inherited share of time deposits across the state space

C.4. Counterfactual – The Model without Time Deposits

To understand the mechanism behind these dynamics, I consider a counterfactual economy in which banks cannot issue time deposits. In this general equilibrium experiment, banks must rely entirely on short-term deposit funding, and all prices and aggregates adjust endogenously. Comparing this counterfactual with the benchmark economy shows how access to time deposits relaxes funding constraints, affects the cost of liquidity, and influences bank failures.

General Equilibrium. Table 7 summarizes the general equilibrium differences between the benchmark model and the counterfactual economy without time deposits.

Removing the option to issue time deposits increases the share of failing banks, from 0.15 percent to 0.30 percent. The absence of a stable, illiquid funding instrument exposes banks more directly to rollover risk, making them more vulnerable to adverse shocks.

Banks respond by deleveraging and operating more conservatively. Average leverage falls from 89.53 percent to 86.42 percent, reflecting balance-sheet adjustments aimed at mitigating liquidity risk in the absence of time deposits.

Consistent with these adjustments, the net interest margin (NIM) declines slightly from 0.99 percent to 0.97 percent. Without access to time deposits, banks rely more heavily on

alternative funding sources, which compresses the spread between lending and deposit rates.

Aggregate lending also declines modestly, from 12.30 to 12.28 model units, corresponding to a reduction of approximately 0.16 percent. The contraction in credit reflects banks' efforts to shrink balance sheets and limit exposure to liquidity shocks.

Together, these results illustrate the key general equilibrium impact of time deposits: while removing time deposits reduces leverage, it increases default risk and slightly compresses intermediation activity. Time deposits therefore play a stabilizing role in the model by allowing banks to manage rollover risk more effectively.

Table 7: Targeted Moments: Benchmark Model, and Counterfactual

Moment	**Benchmark (%)**	**Counterfactual (%)**
Share of failing banks	0.15	0.30
Leverage	89.53	86.42
Share of time deposits	34.79 (9.06)	—
Net interest margin	0.99	0.97
Spread btwn. time dep. and deposit	0.17	—
Lending	12.30	12.28

Note: Standard deviations are shown in parentheses. Model and counterfactual moments correspond to the stationary equilibria of the benchmark and no–time–deposit economies, respectively. Lending values are reported in model units (not percentages).

Leverage Dynamics. Figure C.8 compares the evolution of leverage ratios in the data and in the simulated model around episodes of bank failure, when time deposits are no longer available. Unlike in the benchmark economy, where leverage rises gradually as banks rely on illiquid liabilities to smooth funding shocks, in this counterfactual the absence of time deposits amplifies rollover risk. Without access to long-term funding, banks are forced to rely exclusively on short-term deposits, making them more vulnerable to liquidity shocks, as captured by ω_t. As a result, they actively deleverage in anticipation of rollover risk, leading to a steady decline in leverage well before default. This pattern highlights that time deposits play a critical stabilizing role in the benchmark economy: by reducing debt repayment pressure, they mitigate rollover risk and allow banks to sustain higher leverage levels without immediate default.

Profitability Dynamics. Figure C.9 compares the evolution of the net interest margin

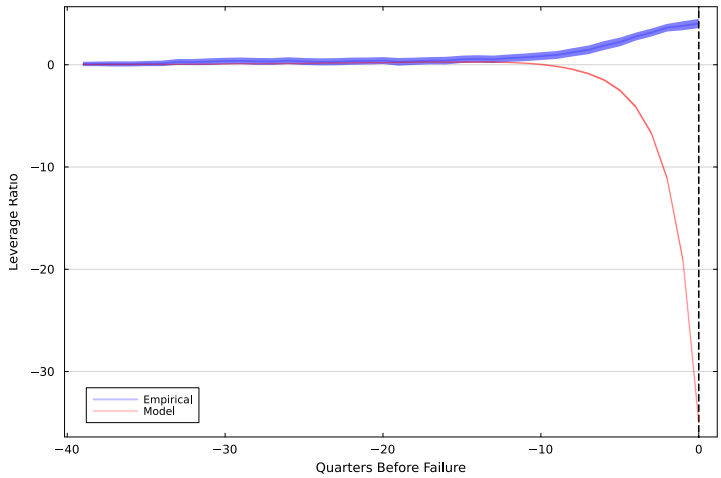

Figure C.8: Leverage (Total Liabilities/Total Assets) Before Bank Failure Counterfactual

(NIM) in the counterfactual economy without time deposits to the empirical pattern observed among failing banks. In the data (blue), NIM remains relatively stable for many quarters prior to failure, declining only gradually as conditions worsen. In the counterfactual model (red), however, profitability deteriorates immediately and declines steadily as the bank approaches default.

Without access to long-maturity time deposits, funding costs become increasingly sensitive to liquidity stress. As rollover risk intensifies and the bank relies exclusively on short-term deposits, deposit rates rise and lending spreads compress. This leads to a persistent and accelerating decline in NIM throughout the pre-failure window. The sharp collapse in NIM immediately before default reflects the bank's inability to smooth funding pressures or maintain stable margins in the absence of illiquid long-term liabilities.

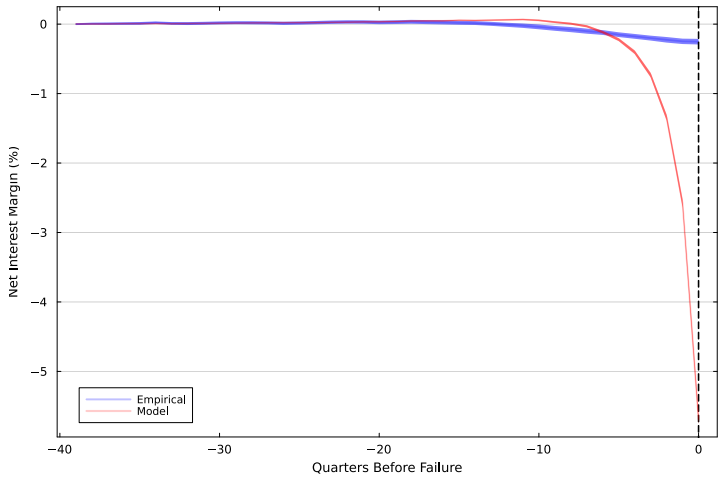

Figure C.9: Net Interest Margin Before Bank Failure Counterfactual

Credit Losses. Figure C.10 compares the evolution of net charge-offs in the counterfactual economy—where time deposits are unavailable—to the empirical pattern. The dynamics of credit losses remain broadly consistent across both settings: charge-offs begin to rise roughly thirty quarters before default, signaling a gradual deterioration in loan performance as banks approach distress, though the onset occurs earlier than in the benchmark model. In the absence of time deposits, however, the increase in charge-offs is somewhat more muted, as banks deleverage sooner and maintain smaller balance sheets. This close correspondence in dynamics, despite differences in leverage and profitability, highlights that deteriorating asset quality is a robust precursor to failure, largely driven by worsening borrower fundamentals rather than by the specific composition of bank funding.

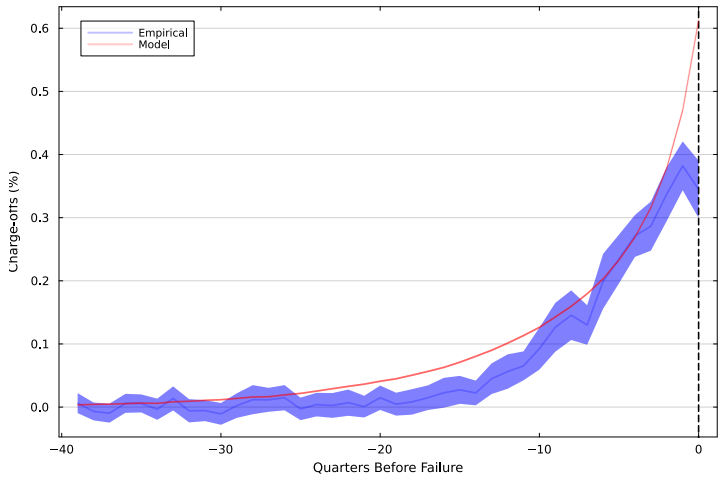

Figure C.10: Net Charge-Offs Before Bank Failure Counterfactual

To understand why the counterfactual without time deposits behaves so differently, Figure C.11 compares the derivative of the value function with respect to liquidity n in the two models, excluding the zero-liquidity point which corresponds to default. Across all economically relevant levels of n, the marginal value of liquidity is strictly higher in the deposit-only model (solid blue). Without access to long-maturity liabilities, banks rely entirely on short-term deposits, making their continuation value much more sensitive to fluctuations in internal liquidity. Even moderate reductions in n sharply increase the likelihood of hitting the constraint, so $\partial V/\partial n$ remains elevated throughout the low- and mid-liquidity region.

By contrast, when time deposits are available (dashed orange), the marginal value of liquidity is uniformly lower. Long-maturity liabilities reduce rollover pressure and relax the funding constraint, so additional liquidity contributes less to the bank's continuation value. Time deposits therefore flatten the liquidity wedge, making banks less fragile to small movements in n and weakening the incentive to engage in defensive deleveraging when liquidity falls.

These counterfactual results highlight the central role of time deposits in stabilizing banks' balance sheets and mitigating liquidity risk. When banks lose access to this form of illiquid funding, their exposure to rollover risk increases sharply, prompting earlier deleveraging and a contraction in balance-sheet size. Although profitability initially improves because core deposit rates are less sensitive to default risk, this gain is short-lived: the absence of stable funding amplifies vulnerability to liquidity shocks and accelerates default. In general

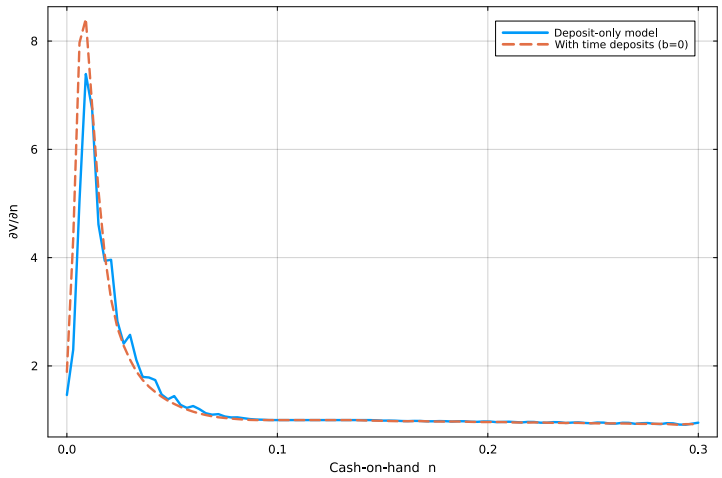

Figure C.11: Derivative of the Value Function with Respect to n

equilibrium, time deposits therefore act as a crucial buffer that enables banks to sustain higher leverage and smoother funding conditions, ultimately reducing the frequency and severity of balance-sheet crises.

C.6. Capital Regulation Without Time Deposits

Table 8: Targeted Moments: Counterfactual Model, and Higher Capital Requirement

Moment	**Counterfactual (%)**	**Higher Capital (%)**
Share of failing banks	0.30	0.28
Leverage	86.42	86.21
Net interest margin	0.96	0.98
Lending	12.28	12.30

Note: Standard deviations are shown in parentheses. Conterfactual model moments correspond to the stationary equilibria of the counterfactual model without time deposits and the same economy with a capital requirement of 8%, respectively. Lending values are reported in model units (not percentages).
